High-beamforming power-code-multiplexed optical scanner for three-dimensional displays

Arain, Muzammil, Riza, Nabeel
Three dimensional (3-D) displays play an important role in the field of entertainment. Today, research is being conducted to produce 3-D displays to meet the complex needs of high-functionality full motion 3D displays at reasonable cost, but without glasses, complicated viewing arrangements or restricted fields of view. Other applications for 3-D displays include but are not limited to CAD/Design simulation, advanced data representation, displaying complex 3-D information for automotive design, medical imaging, advanced navigation displays, scientific visualization, and advertising. The key element in all these applications is an optical beam scanner that can display 3-D images for large viewing angles. Our proposed Code Multiplexed Optical Scanner (C-MOS) can fulfill all these requirements with its high beamforming power capabilities. Our proposed experiment demonstrates three dimensional (3-D) beam scanning with large angles (e.g., > 160°), large centimeter size aperture, and scanning speed of <300 µsec. The robust construction and simple operation of the C-MOS makes it very useful and attractive for deployment in the field of entertainment, defense and medical imaging. Here we report the application of the C-MOS for three dimensional (3-D) displays.

Keywords: 3-D Display, Code Multiplexed Optical Scanner, Holography.
2. C-MOS AND HOLOGRAPHY

Over the years since the invention of the laser, holography has found numerous applications such as in test and measurement, signal processing, entertainment, and image data storage. This paper introduces the use of holography for 3-D inertialess beam scanning using spatial 2-D orthogonal set phase encoding of the input beam. Fig. 1(a) shows the proposed C-MOS concept in the transmissive recording geometry that leads to the generation of an in-line scanning beam. The C-MOS assembly requires the holographic recording of a set of N 3-D scan reference beams with N independent 2-D phase encoded signal beams. Specifically, each 3-D scan beam is recalled by imposing its specific 2-D code on the input laser beam (see Fig. 1 (b) ). Codes and 3-D beam generation optical information can be generated via static optics such as moving mirrors and phase-coded plates and/or by programmable optics such as spatial light modulators (SLM) as shown in Fig. 1.

Fig. 1. C-MOS creation and operation shown where a) shows the hologram recording with changing optical phase codes in a transmissive assembly, and b) shows hologram reading for C-MOS realization in transmissive assembly.
3. C-MOS Experiment

We now describe our proof of concept experiment, in which we have successfully shown the capabilities of C-MOS for 3-D beam steering. Using an orthogonal set of spatial codes (e.g., binary phase only codes or Hadamard codes) implemented through an SLM in the path of the laser input, a set of holograms is recorded in a photorefractive crystal. Here each hologram is stored with a different reference scan beam incident on the holographic material at a different angle. After storing and fixing all the holograms, the scan reference beam is blocked and the spatial codes are regenerated on the input laser beam. Via holographic reconstruction, each spatial code generates its original scan beam that at the exit of the C-MOS creates the output scanned beams. Hence, by cycling through spatial codes, via an SLM, a C-MOS is realized for 3-D scans.

Fig. 2 shows the C-MOS demonstration experimental setup. Collimated light from a 532 nm Nd:YAG laser is s-polarized and expanded using two lenses $L_1$ and $L_2$ making an afocal system with 12.05 magnification. An aperture is used to select the central portion of the collimated beam with uniform intensity. A 50:50 beam splitter is then used to split the incident beam into two beams. One of the beams goes to the reflective optically addressed Parallel Aligned Nematic Liquid Crystal (PAN LC) SLM, reads the coded phase information, and follows the same path through the beam splitter to reach the photorefractive crystal. The other beam (reference) reaches the adjacent face of the photorefractive crystal to record a hologram in 90° geometry through a combination of mirrors $M_1$ and $M_2$ that are used to generate $x$ and $y$ tilts. $L_3$ is a movable weak lens with focal length $f_3$ (75 cm in our case) that is inserted into the path to produce $z$-axis or 3-D translation of a scan beam. The output scanned beam is focused via lens $L_4$ onto the 2-D imaging charge coupled device (CCD). For readout purposes, the reference beam is blocked and corresponding phase code patterns are applied to the SLM driver again to produce the scanning beams in space via holographic reconstruction. The scan speed of the C-MOS is limited by the access time of the SLM, which for the case of the Hamamatsu SLM is a video rate or 30 ms / scan beam.

In our experiment, we recorded and reproduced an 8-beam voxel (see Fig. 3) to show 3-D beamforming capability of the C-MOS. Here we produce a scan angle of ±5° in both $x$ and $y$-direction. By changing the distance between $L_3$ and $L_4$ from 34 cm to 28 cm, a $z$-direction scan of 0.6 cm was obtained. The diameter of the beam was 1.5 cm which demonstrates the large aperture size capabilities of the C-MOS. As mentioned earlier, we use Hadamard codes to store holograms in the holographic medium. In our case, we used the first eight rows of the order 16 Hadamard matrix to store eight beams forming a 3-D voxel element. A higher order, i.e., $16 \times 16$, matrix is used to improve C-MOS operation via selection of optimal 8 codes that give the best experimental crosstalk performance.
In another experiment, to explore the dynamic range of C-MOS scanning capability, we successfully stored and retrieved scanning beams as wide as ±26.5°. This shows that our C-MOS is very effective for the applications where large scanning angles are required. Nevertheless, at present the low diffraction efficiency of the photorefractive crystal is a limitation of the demonstrated C-MOS.

**4. C-MOS BASED 3-D DISPLAY ARCHITECTURE**

The basic building block of the proposed 3-D display is the C-MOS. A schematic diagram of the proposed 3-D display is shown in Fig. 4.
Here electronic control units control the direction of the output beam from the three basic scanning units. As demonstrated before, C-MOS can form a voxel in space. This capability can produce any type of scanning pattern in space. Hence it can be exploited to form desired images to be displayed. As is well known, every color can be produced by the appropriate mixing of three basic colors, i.e., red, green and blue. Light from three lasers, i.e., red, green, and blue are used to produce three color beams. The intensity of these beams can be controlled by the laser power control unit so that all the possible colors can be generated by appropriately mixing these laser beams at any particular point in space. These beams pass through the SLM inside the C-MOS module, takes the appropriate orthogonal phase code for the desired direction implemented via the 3-D image formation control. In the three C-MOS modules, a raster scan pattern is stored in such a way that these scanning units can produce raster scans at different planes. The raster scan produce a 2-D image in x and y direction while the z-position of this raster can be varied by using the z-scan capability of the scanner. Hence a true 3-D image can be generated by scanning point-by-point in space. This arrangement does not require any type of special equipment to see 3-D images and hence can be very useful in 3-D imaging. Moreover, the diffraction efficiency of the C-MOS is usually kept low, and hence it is not dangerous for the naked eye. Note that the output scanned beams are converging spherical beams that intersect at a common point. The intensity of the beams is controlled in such a way that the combined intensity is above threshold of the human eye only at the point where these three beams intersect. Hence an image is formed only at the focal point. By varying the focal length along the z-direction, perception of depth is produced in the 2-D image. Large scan angles and aperture sizes offered by the C-MOS are best suitable for 3-D displays for large size images and large field of views. The ability to recall linear combinations of stored scanned beams can be useful in multiple image generation or high speed operation of 3-D displays.

6. CONCLUSION

In conclusion we have proposed a novel 3-D display based on the C-MOS scanner. C-MOS scanning relies upon retrieval of holographically stored information of the scanning beam/s in a holographic material. C-MOS fabrication is done through storing multiple holograms in any holographic material using orthogonal spatial codes. This system can be implemented for true 3-D displays that do not require special optics to view 3-D images. Also it does not require any software implementation. It is suitable for large aperture and FOV 3-D display applications. This proposed 3-D display is capable of high speed operation along with the possibility of multiple image production. As a first step, a voxel has been generated experimentally to show the 3-D beam forming power of the scanner. Future work relates to implementing three simultaneous C-MOS based scanners to implement a fully colored 3-D display.
