KEYWORDS: Silicon nitride, Silicon Oxide, Atomic Layer Deposition, DFT, mechanisms.

ABSTRACT: Atomic layer deposition (ALD) of highly conformal, silicon-based dielectric thin films has become necessary due to the continuing decrease of feature size in microelectronic devices. The ALD of oxides and nitrides is usually thought to be mechanistically similar, but plasma-enhanced ALD of silicon nitride is found to be problematic, while that of silicon oxide is straightforward. To find why, the ALD of silicon nitride and silicon oxide dielectric films was studied by applying ab initio methods to theoretical models for proposed surface reaction mechanisms. The thermodynamic energies for the elimination of functional groups from different silicon precursors reacting with simple model molecules were calculated using density functional theory (DFT), explaining the lower reactivity of precursors towards the deposition of silicon nitride relative to silicon oxide seen in experiments, but not explaining the trends between precursors. Using more realistic cluster models of amine and hydroxyl covered surfaces, the structures and energies were calculated of reaction pathways for chemisorption of different silicon precursors via functional group elimination, with more success. DFT calculations identified the initial physisorption step as crucial towards deposition and this step was thus used to predict the ALD reactivity of a range of amino-silane precursors, yielding good agreement with experiment. The retention of hydrogen within silicon nitride films but not in silicon oxide observed in FTIR spectra was accounted for by the theoretical calculations and helped verify the application of the model.

INTRODUCTION

Conformal dielectric films based on silicon oxide or silicon nitride are used for liner and spacer applications in front-end-of-line (FEOL) semiconductor wafer processing. The traditional methods for depositing these films have been either plasma enhanced chemical vapor deposition (PECVD) or low pressure chemical vapor deposition (LPCVD). PECVD is capable of depositing semi-conformal films at low temperature (<400°C) and LPCVD is capable of perfectly conformal films at high temperature (>550°C). For sub-32 nm technology however, both low deposition temperature and perfect conformality is required, which has necessitated the move to atomic layer deposition (ALD). Additional applications such as FinFET conformal doping, double patterning, and through-Si-via (TSV) 3D integration are also enabled by ALD of silicon-based dielectrics.

Herein, we focus on two silicon dielectric films: SiO₂ and Si₃N₄. The successful deposition of these materials using ALD techniques is shown in Figure 1, demonstrating that high quality conformal films are possible. Plasma enhanced ALD techniques may be applied in the deposition of these materials where an oxygen plasma is used for SiO₂ and a nitrogen plasma for Si₃N₄. Both ALD silicon oxide and nitride films exhibit the properties desired of these materials with excellent step coverage, good dielectric properties and low wet etch rates. Deposition of these films has also demonstrated reasonable growth rates per ALD cycle if exposure is sufficient. Unfortunately, many experimental problems exist, making the application of the ALD of these silicon dielectrics in industrial processes unfeasible, in particular silicon nitride. These experi-
of silicon nitride but not in ALD of silicon oxide suggests different surface chemistries during deposition. In order to investigate the surface chemistry of these materials, models for the deposition of silicon oxide/nitride have been developed. The prediction of hydrogen incorporation can be used as a way of verifying the mechanistic models.

In this paper, we use first principles density functional theory to prove the reasons behind the differences between the ALD of SiO\textsubscript{2} and Si\textsubscript{3}N\textsubscript{4}. Various theoretical approaches are used including model reaction pathways, acidity/basicity of the oxide vs. nitride surfaces and overall energetics as a function of precursor functional group. A variety of silicon precursors will be taken into account with particular consideration of amino-silane precursors. Amino-silane precursors would be preferred in the ALD of silicon nitride due to the detrimental incorporation of chlorine in films deposited using chloro-silanes. It is assumed that the NH\textsubscript{3} plasma produces an amine-terminated surface, in analogy with the hydroxyl-terminated surface that is produced by oxygen plasma.

**METHOD**

All species in this work were modeled as isolated molecules in vacuum in their ground state using the TURBOMOLE suite of programs\textsuperscript{5,6}. All optimized structures and energies (including those of the transition states) were calculated using the generalized gradient approximation Becke-Perdew density functional BP86\textsuperscript{6,7} with the resolution of identity (RI) approximation\textsuperscript{8-10}. Atom-centered basis sets were used for all atoms in this work: the large def2-TZVPP basis set for amines, hydronium, and H\textsubscript{2}O while the substitution of OH groups for the ligands represents the formation of new M–O bonds in the solid. Here, in order to model the elimination of groups from functionalized silane precursors SiH\textsubscript{2}X\textsubscript{2}, the hydrosilation model is modified so that only elimination of two functional groups (X) is considered during the ALD of silicon oxide (Equation 1a). An equation to represent surface reactivity on silicon nitride is proposed where gas-phase ammonia (NH\textsubscript{3}) represents NH bonds on the surface (analogous to H\textsubscript{2}O representing surface hydroxyl groups) and the substitution of amide groups (NH\textsubscript{2}) for the functional groups, X, represents the formation of new Si–N bonds (Equation 1b).

The elimination of H–L from a surface has been successfully modeled previously for the ALD of metal oxides using a gas phase hydrosilation model\textsuperscript{14}. ∆E\textsubscript{hyd} is the computed energy change of the following model reaction: ML\textsubscript{n}\textsubscript{(g)} + qH\textsubscript{2}O\textsubscript{(g)} → M(OH)\textsubscript{n}\textsubscript{(g)} + qHL\textsubscript{(g)}, where M is a metal of valence q and L is a monodentate ligand. In this model gas-phase H\textsubscript{2}O represents the source of hydroxyl groups on the surface of the metal oxide while the substitution of OH groups for the ligands represents the formation of new M–O bonds in the solid. Here, in order to model the elimination of groups from functionalized silane precursors SiH\textsubscript{2}X\textsubscript{2}, the hydrosilation model is modified so that only elimination of two functional groups (X) is considered during the ALD of silicon oxide (Equation 1a). An equation to represent surface reactivity on silicon nitride is proposed where gas-phase ammonia (NH\textsubscript{3}) represents NH bonds on the surface (analogous to H\textsubscript{2}O representing surface hydroxyl groups) and the substitution of amide groups (NH\textsubscript{2}) for the functional groups, X, represents the formation of new Si–N bonds (Equation 1b). This model reaction is referred to in this work as "hydrosilation" for the deposition of silicon oxide and "amination" when considering silicon nitride deposition. 

\[
\Delta E_{\text{hyd}} = \frac{\Delta E}{2}: \text{SiH}_2X_2(g) + 2\text{H}_2\text{O}(g) \rightarrow \text{SiH}_2(\text{OH})_2(g) + 2\text{HX}(g)
\]  
(1a)

\[
\Delta E_{\text{amin}} = \frac{\Delta E}{2}: \text{SiH}_2X_2(g) + 2\text{NH}_3(g) \rightarrow \text{SiH}_2(\text{NH}_2)_2(g) + 2\text{HX}(g)
\]  
(1b)

**Figure 2:** Deposition rate versus exposure of SiO\textsubscript{2} (red diamonds) and Si\textsubscript{3}N\textsubscript{4} (green circles) films deposited from chloro-silane precursors by ALD at 450 °C.

Of specific interest is the experimental observation that the required silicon precursor exposure is significantly (>100 ×) higher for Si\textsubscript{3}N\textsubscript{4} than for SiO\textsubscript{2}. Figure 2 compares the relative reactivity for simple chloro-silane precursors (e.g. DCS, HCDS, etc.) while similar data (not shown) has been obtained using amino-silane precursors (e.g. BTBAS, BDEAS, etc.). The very long precursor exposure for deposition of silicon nitride makes this process economically unviable, due to both the excessive throughput time per film deposited and the unacceptably high volume of silicon precursors consumed. It is the goal of this work to explain the difference in deposition efficiency for a given exposure between SiO\textsubscript{2} and Si\textsubscript{3}N\textsubscript{4} and to examine the effect of different silicon precursor on deposition efficiency.

**Figure 3:** FTIR absorption spectra of SiO\textsubscript{2} (upper red plot) and Si\textsubscript{3}N\textsubscript{4} (lower green plot) thin films both deposited by ALD at >400°C.

Representative FTIR data are shown in Figure 3. One of the marked differences between these spectra is the lack of bands associated with hydrogen (Si–O–H) in SiO\textsubscript{2}. In Si\textsubscript{3}N\textsubscript{4} a peak assigned to NH stretching modes can be clearly observed at 3350 cm\textsuperscript{-1}, whereas the equivalent OH stretching modes in SiO\textsubscript{2} are non-existent. The incorporation of hydrogen in ALD
In equations 1a and 1b, $\Delta E$ is quoted per functional group X. The more negative a $\Delta E_{\text{expt}}$ or $\Delta E_{\text{calc}}$ value is, the more exothermic the hydrolysis/amination reaction and the greater the possibility of HX elimination. As this model is concerned solely with the changes in bonding, temperature effects are neglected.

In many cases, the activation energies and surface geometries are important in determining the reactivity of a molecule at a surface and so the model proposed in Section 2.1 is not adequate. The proposed mechanism for the reactive chemisorption of a SiH$_2$X$_2$ precursor is (i) physisorption, (ii) proton transfer via a transition state followed by (iii) HX elimination$^{15}$. The various steps required to model this process are described in Figure 4.

Figure 4: The proposed mechanistic steps for reactive chemisorption of SiH$_2$X$_2$ precursor and desorption of functional group X via proton transfer from a Si–Y–H functionalized surface (Y = O, NH or N).

The first step in Figure 4 shows the "Unbound Reactants" (UR) where the precursor SiH$_2$X$_2$ is isolated, by an effectively infinite distance, from a surface group Y–H (where Y = O, NH or N). In the second "Bound Reactants" (BR) step, a loosely bound complex is formed between a group X on the precursor and a surface hydrogen atom. Direct coordination of the Si precursor to surface-Y via dative bonding is not expected in this mechanism because Si does not tend to increase its coordination number beyond four in stable structures. This BR structure leads into a four-membered ring "Transition State" (TS) involving the Si and X on the precursor and Y and H on the surface. With five-fold coordination about Si in TS, this structure is expected to be unstable and transient. Step 4 describes the "Bound Products" (BP) where the precursor is now chemisorbed to the surface but the newly formed molecule H–X is still hydrogen bonded to Y. Step 5 in Figure 4 shows the final "Unbound Products" (UP) where H–X has been fully eliminated from the surface and the SiH$_2$X group bound to the surface has relaxed to its most stable structure.

RESULTS AND DISCUSSION

Figure 5: Molecular structures of some of the silicon precursors considered in this work. Structures were optimized using BP86/TZVPP. The silicon atoms are represented by yellow spheres, hydrogen by white, nitrogen by blue, oxygen by red, carbon by grey and chlorine by green.

In the following sections, results from the application of the theoretical models described in above will be given. Multiple di-alkylamide silanes with the general formula SiH$_2$(NR'R'')$_2$ were considered including: SiH$_2$DMA$_2$ [R'=R''=CH$_3$, bi(dimethylamino)silane], SiH$_2$HFMA$_2$ [R'=R''=CF$_3$, bis(hexafluorodimethylamino)silane], SiH$_2$EMA$_2$ [R'=R''=CH$_3$, R''=CH$_2$CH$_3$, bis(ethylmethylamino)silane], BDEAS [R'=R''=CH$_3$CH$_2$ bis(diethylamino)silane], and BTBAS [R'=C(CH$_3$)$_3$, R''=CH$_3$, bis(tert-butylamino)silane] as well as SiH$_2$(NH$_2$)$_2$ [diamino-silane] and DIHAS [diisopropylamino-silane] with only one amide functional group with R'=R''=CH$_2$CH$_3$ attached to the silyl SiH$_3$ group. Some results for other silanes including SiH$_2$Cl$_2$ [dichlorosilane], SiH$_2$(CH$_3$)$_2$ [dimethylsilane] and SiH$_4$ [silane] will also be given. The molecular structures of these precursors are shown in Figure 5.

The molecular structures for a selection of silicon precursors and the molecules (SiH$_2$(NH$_2$)$_2$ and SiH$_2$(OH)$_2$ respectively) employed to model the silicon nitride and oxide surfaces were optimized using BP86/TZVPP. The resulting geometries are depicted in Figure 5. The functional groups are coordinated to the silicon atom in a quasi-tetrahedral fashion, exemplified by the SiH$_4$ parent molecule. Some distortion from this idealized coordination is seen for SiH$_2$HFMA$_2$, SiH$_2$EMA$_2$, BDEAS and BTBAS molecules due to the relatively large size of the functional group and for SiH$_2$(OH)$_2$ due to intra-molecular interactions between the two OH groups. Optimization of the same molecules using the SV(P) basis set resulted in similar geometries.
The ΔE values for both the hydrolysis and amination of a selection of silicon precursors were determined from Equations 1a and 1b using DFT calculated energies (BP86/TZVPP) and are presented in Figure 6. ΔE_{hydrolysis} was significantly more negative than ΔE_{amination} by 47.14 kJ/mol (this value is actually |ΔE| of SiH₃(NH)₂ + 2H₂O ↔ SiH₃(OH)₂ + 2NH₃). This result predicts that functional group elimination from di-functionalized silane precursors is thermodynamically more favorable on OH-covered SiO₂ surfaces than on NH₂/NH-covered Si₃N₄ surfaces. This appears to correlate with the much slower ALD growth rates for silicon nitride compared with silicon dioxide. Unfortunately, the limitations of this thermodynamic model become apparent when the trends between the different precursors are considered. SiH₂(CH₃)₂ and SiH₄ are predicted here to be the most reactive and SiH₂Cl₂ the least reactive. These theoretical predictions are contradicted experimentally where SiH₂(CH₃)₂ and SiH₄ are not precursors for the ALD of either SiO₂ or Si₃N₄ due to slow or negligible growth rates. SiH₂Cl₂ is one of the more promising precursors, in particular for the deposition of Si₃N₄, and has demonstrated significant ALD growth rates in experiment. Even for the alkyl amides (SiH₂DMA₂, SiH₂EMA₂, BDEAS and BTBAS), greater variation in deposition rates is seen in experiments than compared to the theoretical results presented in Figure 6. A kinetic model, considering energy barriers and surface geometries, is therefore needed to explain the differences between silicon amide precursors in the deposition of silicon nitride and dioxide.

Simple surface models consisting of one functional group of interest were investigated. The silyl group SiH₃ was selected to represent both the SiO₂ and Si₃N₄ bulk material. To model hydroxyl groups on SiO₂, an OH group was added to the SiH₃ fragment resulting in a SiH₃−OH (silanol) surface model. For the nitride models, either NH₂ was added to SiH₃ to represent a primary amine, resulting in a SiH₃−NH₂ (silylamine) surface model or NH−SiH₃ to model secondary amides, a SiH₃−NH−SiH₃ (distylylamine) surface model. Two precursors were initially considered, SiH₃(NH)₂ and SiH₂DMA₂, due to their small size, reducing the computation resources required and allowing easy analysis of the resulting structures. All SiH₃−YH results presented here were calculated using the BP86 GGA density functional and SV(P) basis set.

**Figure 6:** ΔE for the hydrolysis (YH = H₂O) and amination (YH = NH₃) of various silicon precursors calculated using equations 1a and 1b from BP86/TZVPP total energies.

The optimized geometries and energies for the proton transfer steps (outlined in Figure 4) from SiH₃−NH−SiH₃, SiH₃−NH₂ and SiH₃−OH to one of the functional groups of SiH₂(NH)₂ and SiH₂DMA₂ were calculated. The transition state (TS) geometries from these calculations are shown in Figure 7. For these transition states a planar, "kite" shaped 4-membered ring is found between the O/N and H of the surface model molecule and the N and Si of the incoming precursors. The orientation of the precursors towards the surface models is different for each group. While the precursors may approach SiH₃−OH vertically to form a transition state, a side-on approach of the precursors is necessary for the SiH₃−NH₂ due to the orientation of the amine hydrogen atoms. This seems to reflect the direction of the lone pair on O and N respectively.

**Figure 7:** DFT optimized structures of the transition states for the reactions of SiH₂(NH)₂ and SiH₂DMA₂ silicon precursors with SiH₃−NH−SiH₃, SiH₃−NH₂ and SiH₃−OH surface models. The silicon atoms are represented by yellow spheres, hydrogen by white, nitrogen by blue, oxygen by red and carbon by grey. The bonds of the 4-membered ring transition state are highlighted in yellow.

**Figure 8:** Energetics for the Bound Reactants (BR), Transition State (TS), Bound Products (BP) and Unbound Products (UP) relative to the Unbound Reactants (UR) for the reaction of a. SiH₂(NH)₂ and b. SiH₂DMA₂ precursor with the surface group models SiH₃−OH (red diamonds), SiH₃−NH₂ (green squares) and
SiH$_3$−NH−SiH$_3$ (blue triangles). ∆E values are given in kJ/mol and were determined using BP86/SV(P) DFT calculations.

![Figure 9: (Si$_3$N$_6$)$_4$ cluster model (upper center) with NH$_3$/H terminated (Si$_3$N$_6$)$_4$(NH$_3$)$_2$ cluster (lower left) and OH/H terminated (Si$_3$N$_6$)$_4$(H$_2$O)$_2$ cluster (lower right).](image)

A cylindrical silicon nitride cluster consisting of 4 SiN$_4$ stoichiometric units (Si$_{12}$N$_{16}$ with 28 atoms) was constructed, based on the chemically stable, β-phase crystal structure with hexagonal symmetry$^{[15]}. To this bare cluster, 12 NH$_2^−$ anions and 12 H$^+$ cations were added, terminating the uncoordinated Si and N atoms respectively on the outside of the cluster. This had the effect of adding 12 NH$_3$ molecules to the cluster, retaining the neutral charge of the cluster. This (Si$_3$N$_6$)$_4$(NH$_3$)$_2$ cluster (Si$_{12}$N$_{16}$H$_{12}$(NH$_3$)$_2$ with 76 atoms) was used to model ALD reactions of silicon precursors at a Si$_3$N$_4$ surface. The model used for reactions at a silicon oxide surface was constructed in a similar fashion to the silicon nitride, where 12 OH$^−$ and 12 H$^+$ fragments (i.e. 12 H$_2$O molecules) were added to the Si$_{12}$N$_{16}$ cluster resulting in a (Si$_3$N$_6$)$_4$(H$_2$O)$_2$ cluster (Si$_{12}$N$_{16}$H$_{12}$(OH)$_2$ with 64 atoms). Although SiO$_2$ has a different crystal structure than Si$_3$N$_4$, the use of the same (Si$_3$N$_6$)$_4$ core for both silicon dioxide and nitride models allowed direct comparison of many calculated properties e.g. changes in geometry between reaction steps.

The geometries of both (Si$_3$N$_6$)$_4$(H$_2$O)$_2$ and (Si$_3$N$_6$)$_4$(NH$_3$)$_2$ clusters were optimized using the BP86 DFT functional and SV(P) basis set. The resulting structures are shown in Figure 9 with only minor changes to the underlying (Si$_3$N$_6$)$_4$ cluster seen during the optimizing process. Optimization of the various structures corresponding to the reaction steps outlined in Figure 4, was attempted for the SiH$_3$(NH$_2$)$_2$ and SiH$_2$DMA$_2$ precursors with both the (Si$_3$N$_6$)$_4$(H$_2$O)$_2$ and (Si$_3$N$_6$)$_4$(NH$_3$)$_2$ surface models, using the same method as for the smaller SiH$_3$−XH models (BP86/SV(P)). Only reactions of precursors with NH$_2$ and OH groups were considered due to the relative inaccessibility of the secondary, NH amine groups on the cluster.

![Figure 10: BP86/SV(P) optimized geometries of Bound Reactants, Transition State and Bound Products structures for SiH$_2$DMA$_2$ with a, (Si$_3$N$_6$)$_4$(NH$_3$)$_2$ as a model for silicon nitride growth and b, (Si$_3$N$_6$)$_4$(H$_2$O)$_2$ as a model for silicon oxide growth.](image)

The structures determined for both SiH$_2$DMA$_2$ and SiH$_2$(NH$_2$)$_2$: amide precursors were quite similar. Figure 10 depicts the geometries determined for the BR, TS and BP steps of the SiH$_2$DMA$_2$ reaction with cluster model surfaces. The structures calculated for the reaction steps are qualitatively similar to those determined using the SiH$_3$−YH models with a few notable differences. In the BR and TS steps of SiH$_2$DMA$_2$ on (Si$_3$N$_6$)$_4$(NH$_3$)$_2$, there is an increased steric interaction between one of the CH$_3$ groups on the reacting DMA fragment and the cluster surface. A side-on orientation of the reacting precursor alkyl amide group with respect to the surface...
means that only one CH\textsubscript{3} group of DMA interacts strongly with the surface while the other points away. For reactions involving SiH\textsubscript{2}(NH\textsubscript{2})\textsubscript{2}, these steric interactions are reduced due to the smaller NH\textsubscript{2} precursor groups. The favorable orientation of hydroxyl groups on the (Si\textsubscript{3}N\textsubscript{4})(H\textsubscript{2}O)\textsubscript{12} cluster also reduces the steric interactions.

The ΔΕ[BR] values calculated for a series of precursors bound to either (Si\textsubscript{3}N\textsubscript{4})(NH\textsubscript{2})\textsubscript{12} or (Si\textsubscript{3}N\textsubscript{4})(H\textsubscript{2}O)\textsubscript{12} surface models are tabulated in Table 2. In all cases ΔΕ[BR] for adsorption onto the oxide model surface (Si\textsubscript{3}N\textsubscript{4})(H\textsubscript{2}O)\textsubscript{12} is significantly lower than that onto the nitride model (Si\textsubscript{3}N\textsubscript{4})(NH\textsubscript{2})\textsubscript{12}. The most exothermic ΔΕ[BR] value determined for (Si\textsubscript{3}N\textsubscript{4})(H\textsubscript{2}O)\textsubscript{12} was for the SiH\textsubscript{2}(NH\textsubscript{2})\textsubscript{2} precursor, gradually increasing to the least reactive, BDEAS. A greater variation in relative reactivity was determined for the same amino-silane precursor with (Si\textsubscript{3}N\textsubscript{4})(NH\textsubscript{2})\textsubscript{12} than seen for (Si\textsubscript{3}N\textsubscript{4})(H\textsubscript{2}O)\textsubscript{12}. As described above in Section 4.2, the difference in ΔΕ[BR] between SiH\textsubscript{2}(NH\textsubscript{2})\textsubscript{2} and SiH\textsubscript{2}DMA\textsubscript{2} was primarily due to the difference in size between the functional groups, the smaller hydrogen atom in SiH\textsubscript{2}(NH\textsubscript{2})\textsubscript{2} reduced steric interactions compared with the larger methyl groups of SiH\textsubscript{2}(DMA\textsubscript{2}). The substantially different ΔΕ[BR] values of about -21.4 and -5.8 kJ/mol determined for BTBAS and BDEAS on the nitride substrate are, at first glance, surprising considering that they have the same number of constituent atoms. Examining the molecular structure of these precursors (see Figure 5), the presence of NH in the BTBAS allows the alkyl amide functional group to approach surface NH\textsubscript{2} groups with relatively low steric hindrance, comparable to the much smaller SiH\textsubscript{2}(NH\textsubscript{2})\textsubscript{2}. It is therefore possible to combine large R groups for volatility with accessible NH groups for adsorption in precursors of the type SiH\textsubscript{2}(NH\textsubscript{2})\textsubscript{2}. BDEAS, unlike BTBAS, has two ethyl groups on each of its alkyl amide functional groups, resulting in steric interactions similar to SiH\textsubscript{2}DMA\textsubscript{2}, decreasing the stability of this BR complex. Although DIPAS has only one alkyl amide attached to its central silicon atom, the large isopropyl groups interact in a similar manner to the alkyl groups of SiH\textsubscript{2}DMA\textsubscript{2} and BDEAS creating steric hindrance around the reacting site.

![Figure 11: Energetics for the Bound Reactants (BR), Transition State (TS), Bound Products (BP) and Unbound Products (UP) relative to the Unbound Reactants (UR) for the reaction of SiH\textsubscript{2}(NH\textsubscript{2})\textsubscript{2} (triangles, dashed lines), SiH\textsubscript{2}DMA\textsubscript{2} (squares, solid lines) with the cluster models (Si\textsubscript{3}N\textsubscript{4})(NH\textsubscript{2})\textsubscript{12} (red) and (Si\textsubscript{3}N\textsubscript{4})(H\textsubscript{2}O)\textsubscript{12} (green). The table inset presents the E\textsubscript{act} values for the precursors with the NH\textsubscript{2} and OH covered surfaces. ΔΕ values are given in kJ/mol and were determined from BP86/SV(P) DFT calculations.

Table 2: Energy difference calculated between Unbound Reactants (UR) and Bound Reactants (BR) structures, ΔΕ[BR] = $E$(UR) - $E$(BR), for SiH\textsubscript{2}(NH\textsubscript{2})\textsubscript{2}, SiH\textsubscript{2}DMA\textsubscript{2}, BTBAS, BDEAS and DIPAS precursors and (Si\textsubscript{3}N\textsubscript{4})(NH\textsubscript{2})\textsubscript{12} and (Si\textsubscript{3}N\textsubscript{4})(H\textsubscript{2}O)\textsubscript{12} cluster models. Energy values (in kJ/mol) were determined using BP86/SV(P) calculations.

The relative energies of the mechanism steps for the three model precursors with the NH\textsubscript{2} and OH covered clusters are plotted in Figure 11. The $E_{act}$ barriers are comparable to those determined using the smaller SiH\textsubscript{3}−NH\textsubscript{2} and SiH\textsubscript{3}−OH models. The reduction in energy from BP to UP steps for SiH\textsubscript{2}(NH\textsubscript{2})\textsubscript{2} reactions with both surfaces and SiH\textsubscript{2}DMA\textsubscript{2} with (Si\textsubscript{3}N\textsubscript{4})(H\textsubscript{2}O)\textsubscript{12} is due to the removal of the hydrogen bonded NH\textsubscript{3} and H-DMA molecules. This allows the newly formed surface SiH\textsubscript{2}NH\textsubscript{2}/SiH\textsubscript{2}DMA\textsubscript{2} groups to relax to more stable structures that were prohibited by the presence of the H-bonded amine molecules in the Bound Products structures.

One of the most striking differences between these larger cluster calculations and those of the SiH\textsubscript{3}−YH models, is the widespread now apparent in the BR energies relative to UR (Figure 11). This energy difference is the adsorption energy. The larger steric interactions experienced by SiH\textsubscript{2}DMA\textsubscript{2} with the amine-covered surface compared with the hydroxyl-covered surface destabilize BR. The same steric interactions explain the weaker adsorption by SiH\textsubscript{2}DMA\textsubscript{2} relative to SiH\textsubscript{2}(NH\textsubscript{2})\textsubscript{2} on both substrates. The higher energy of BR reflects a reduced bond strength of the precursor to the surface. This may increase the probability of the precursor retreating unreacted to the gas phase at ALD temperatures and may prevent the remaining reaction steps occurring. This initial BR step is therefore crucial in determining the deposition rate of a precursor and was chosen as a metric for ALD reactivity of other potential precursors.
The presence of intense absorption bands, assigned to NH stretching and bending modes, in FTIR spectra of Si$_3$N$_4$ compared to the absence of OH bands in SiO$_2$ is one of the notable differences observed between ALD-grown silicon nitride and silicon dioxide. This retention of hydrogen in silicon nitride films may be explained by looking at the final unbound products (UP) calculated using the proton transfer mechanism described in this work. The molecular structure shown in Figure 12a depicts a SiH$_2$DMA$_2$ product chemisorbed to a (Si$_3$N$_4$)(H$_2$O)$_{12}$ surface after the elimination of an H-DMA molecule. The new silicon atom from the precursor is bonded to the surface via an oxygen atom which in turn is bonded to a Si atom of the bulk substrate (Si−O−Si), leaving no H atoms coordinated to the oxygen. Elimination of the other DMA group as H-DMA may further deplete the surface of hydrogen, forming a second Si−O−Si bridge.

Considering the product from the same precursor onto the (Si$_3$N$_4$)(NH$_3$)$_{12}$ cluster in Figure 12b, the incoming silicon atom is bonded to the surface via a nitrogen and then to a substrate silicon atom. However, unlike the SiO$_2$ model, the nitrogen atom bridging the new silicon atom with the underlying surface has a remaining hydrogen atom (Si−NH−Si) where elimination of the other DMA group would form another Si−NH−Si bridge. Further adsorption of a second precursor to bridging NH group and removal of second hydrogen during the silicon precursor ALD pulse is prevented by steric hindrance from the first precursor fragment, particularly in attempting to form the four-membered ring TS (Figure 10). In this way, despite removal of DMA by the nitrogense pulse (e.g. by treatment with NH$_3$ plasma), this NH group will be buried within the film and will remain even after annealing.

**CONCLUSIONS**

Silicon nitride films deposited using ALD with silicon precursors and NH$_3$ plasma require a precursor exposure more than 100 times greater than that for silicon oxide films deposited with oxygen plasma. Experiments also show significantly different deposition rates between the precursors employed in the deposition of silicon nitride. In order to explain these differences, various theoretical models employing DFT calculations have been applied. Thermodynamic models using DFT calculated energies correctly predict the lower reactivity of silicon precursors with amine-terminated surfaces compared to hydroxylated surfaces, but failed to predict the trends in reactivity between precursors. A mechanistic pathway for growth involving the elimination of a precursor functional group via proton transfer mechanism was applied first to small molecules representing surface groups and then to larger cluster models of silicon nitride and silicon oxide surfaces. A significant difference in reactivity is observed due to the orientation of the hydrogen atoms attached to the hydroxyl and amine groups, where in-coming precursors approach the OH group vertically and approach the NH$_2$ group side-on. The nitride surface is therefore considerably more sensitive to precursor bulk.

The significance of this difference in approach of the precursors towards the surface groups becomes apparent when reactivity with the larger cluster models is considered. For the OH covered surface little interaction is observed between the precursor and surrounding surface, but for the NH$_2$ covered surface, the side-on approach of the precursor causes the precursor groups to be oriented towards the surface. This has a substantial effect on the strength of the H-bonding between precursor and surface ("Bound Reactants") and thus on the lifetime of the adsorbed state and the probability of further reaction before desorption. Their relative adsorption energetics are therefore used to estimate the ALD kinetics and exposure required. With regard to the silicon dioxide surface models, all the amino-silane precursors considered in this work were determined to have reasonably strongly bound reactants (adsorption energies between −32 and −65 kJ/mol) and therefore a reasonable ALD growth rate is predicted. The steric bulk of the amine functional groups attached to the precursors was found to have a greater effect on ALD growth of silicon nitride.

For the precursors where one or more smaller R groups were attached to the amine functional groups (e.g. SiH$_2$(NH$_2$)$_2$, $E_{\text{BR}}$($\text{AgN}1\text{S}1$) = −28.2 kJ/mol), more stable bound reactants structures were found than those with larger R groups (e.g. BDEAS, $E_{\text{BR}}$($\text{AgN}1\text{S}1$) = −5.9 kJ/mol). DFT calculations for the bound reactants of the larger SiH$_2$DMA$_2$ and BDEAS precursors yielded the lowest adsorption energies −7.5 and −5.8 kJ/mol. Despite the same number of atoms as BDEAS and a large t-butyl group attached to one position of the amine functional groups, adsorption of BTBAS (−21.4 kJ/mol) was determined to be significantly more exothermic than that of BDEAS (−5.8 kJ/mol). In facts BTBAS adsorbs as easily as the model precursor SiH$_2$(NH$_2$)$_2$ (−28.8 kJ/mol) where the presence of the small hydrogen on the amine functional group allows the precursors to form bound reactant structures with reduced steric interactions with the surrounding surface compared to larger alkyl groups.

The mechanism presented in this work for the adsorption of silicon precursors via functional group elimination predicts hydrogen atoms to be present both on the surface and embedded within the growing silicon nitride film. By contrast, the same mechanism predicts that hydrogen is only present on the surface of silicon oxide film. In the experimental FTIR absorption spectra, vibrational bands associated with NH bonds in silicon nitride are indeed detected, in contrast with a lack of OH vibrational bands in silicon oxide. This helps validate the proposed growth mechanism and theoretical approach. Due the relative unreactivity of NH...
groups towards functional group elimination, the plasma assisted ALD silicon nitride is much slower compared to that of silicon oxide systems and requires longer precursor exposure. Targeted reduction in precursor bulk may improve the situation, but the main reason is the inflexible orientation of amine groups at the surface, which is an intrinsic property of the silicon nitride material being deposited.
