Efficient one-pot synthesis of highly monodisperse carbon quantum dots

Keith Linehan and Hugh Doyle*

Highly luminescent carbon quantum dots (CQDs) with narrow size distributions were synthesised in reverse micelles using a simple room temperature, solution-phase synthesis. The CQDs are stabilised by covalently bound alkyl ligand to minimise surface oxidation and exhibit blue emission with a marked dependency on excitation wavelength.

The recent emergence of carbon quantum dots (CQDs) as a versatile fluorescence nanomaterial has garnered widespread interest due to their attractive photophysical properties, high quantum yields, low toxicity and biocompatibility.1,2 Compared to conventional organic dyes and semiconductor nanocrystals, CQDs possess several advantages in terms of chemical inertness, easy functionalisation, high resistance to photobleaching, an absence of fluorescence intermittency and the potential for low cost production. As a result, much attention has been paid to their potential application in areas from biological labelling and imaging to fluorescence nanosensors and optoelectronic devices.2,4 A number of different synthetic strategies have been developed and reported for the preparation of CQDs, which may be divided into physical and chemical methods. Physical methods include arc discharge,6 laser ablation/passivation,7,8 and plasma treatment.9 Chemical methods include electrochemical synthesis,10 combustion and acidic oxidation,13,14 hydrothermal and pyrolysis routes,15 supported synthesis16–18 and microwave/ultrasonic synthesis.19,20 However, some drawbacks associated these methods include extensive post-synthetic purification, lack of control of CQD surface chemistry and sample polydispersity. To date, it has been proven difficult to produce ultra-small monodisperse CQDs with narrow size distributions, with many methods still requiring the need for impractical size separation processes to obtain monodisperse CQDs.1

The use of solution-based synthetic methods have been the most promising due to their ability to control the size, shape and surface chemistry of the CQDs. Rhee and co-workers reported the solution-phase synthesis of CQDs using reverse micelles as nanoscale reactors.21 The CQDs were formed via condensation polymerisation and subsequent carbonization of glucose within AOT reverse micelles at 160 °C. Control of the water-surfactant ratio within the micelle allowed the CQD diameter to be tuned from 1.8 to 4.1 nm, but with increasing polydispersity at larger diameters. They later reported a similar hydrothermal synthesis of nearly monodisperse (1.4 ± 0.15 nm) CQDs using octanol as the surfactant.22 In both cases, subsequent in situ surface passivation resulted in formation of hexadecylamide-capped CQDs. More recently, Gao et al. reported on the hydrothermal synthesis of CQDs by oxidation of C60 by hydrogen peroxide under alkaline conditions within CTAB reverse micelles at 150 °C.23

In this communication, we report a simple one-pot, solution phase synthesis of highly monodisperse, alkyl-capped, brightly luminescent CQDs formed by chemical reduction of carbon precursors in reverse micelles. This single-phase, room temperature method is inspired by our previously reported syntheses of size monodisperse Group IV nanocrystals.24,25 The overall synthetic procedure is illustrated in Scheme 1. Under inert atmospheric conditions, carbon tetrachloride is dissolved within the hydrophilic interior of a tetroxacyl ammonium bromide (TOAB) reverse micelle; the carbon source material is then readily reduced using lithium aluminium hydride to form hydrogen-terminated CQDs confined within the micelle interior. The surface of the as-synthesised CQDs is then modified using a platinum-catalysed process to form C–C bonds, which chemically passivates the CQD surface to minimise oxidation.

Scheme 1 Schematic of the chemical synthesis and surface passivation of highly monodisperse dodecane-capped CQDs.

Fig. 1(a) shows a transmission electron microscope (TEM) image of the as-synthesized CQDs. The CQDs are highly size and shape monodisperse with no evidence of aggregation, see Fig 1 and S1 of ESI. Inset in Fig. 1(a) is a high resolution TEM image showing that the CQDs are highly crystalline with a lattice spacing of 2.1 Å, in excellent agreement with the (100) spacing reported for graphitic carbon. Fig. 1(b) shows a histogram of the CQD diameters, determined by analysis of TEM images of ca. 250 CQDs located at different locations on the grid. The mean diameter of the CQDs is 1.5 ± 0.3 nm, based on fitting the histogram to a Gaussian model.

The surface chemistry of the quantum dots was characterized by infrared spectroscopy; Fig. 2 shows the FTIR spectra of 1-dodecene (blue line) and the as-synthesised CQDs (red line). The dotted lines indicate the vinyl (R-CH=CH₂) stretching and bending vibrations.

The optical properties of the CQDs were investigated using UV-visible and photoluminescence spectroscopy. Fig. 3(a) shows the absorbance and photoluminescence spectra of the dodecane-capped CQDs in hexane. The absorption spectrum shows a peak centred at 264 nm with an onset of absorbance at 370 nm. This is in excellent agreement with reports of graphitic carbon CQDs strongly absorbing in the UV region. The photoluminescence spectra were obtained using excitation wavelengths ranging from 280 to 400 nm in 10 nm increments. The wavelength position of the PL maximum ranges from 325 nm for excitation at 280 nm to 450 nm for 400 nm excitation. This corresponds to an overall red shift in the PL peak position of 125 nm, as the excitation wavelength is increased by 120 nm; see Fig. 3(b). This clear dependency on excitation wavelength has also been widely observed for CQDs prepared using different methods of preparation and surface functionalities.¹⁻³

To date, the origin of luminescence for CQDs remains controversial and complicated due to the wide variety of methods reported, together with the different ligand schemes, surface oxidation and broad particle size distributions which all contribute to the lack of consensus.¹⁻³ The wavelength dependency has been mainly attributed to optical selection of
The high degree of surface passivation may also contribute to the narrow PL spectra (FWHM: 60 nm) observed. The CQDs also exhibit excellent long-term PL stability, decreasing by less than 4% after continuous illumination for 12 hours; see Fig S2.
