First-principles calculation of carrier-phonon scattering in \( n \)-type Si\(_{1-x}\)Ge\(_x\) alloys

F. Murphy-Armando and S. Fahy

Department of Physics and Tyndall National Institute, University College Cork, Cork, Ireland

(Received 30 January 2008; revised manuscript received 29 April 2008; published 3 July 2008)

First-principles electronic structure methods are used to find the rates of inelastic intravalley and intervalley \( n \)-type carrier scattering in Si\(_{1-x}\)Ge\(_x\) alloys. Scattering parameters for all relevant \( \Delta \) and \( L \) intra- and intervalley scattering are calculated. The short-wavelength acoustic and the optical phonon modes in the alloy are computed using the random mass approximation, with interatomic forces calculated in the virtual crystal approximation using density functional perturbation theory. Optical phonon and intervalley scattering matrix elements are calculated from these modes of the disordered alloy. It is found that alloy disorder has only a small effect on the overall inelastic intervalley scattering rate at room temperature. Intravalley acoustic scattering rates are calculated within the deformation potential approximation. The acoustic deformation potentials are found directly and the range of validity of the deformation potential approximation verified in long-wavelength frozen phonon calculations. Details of the calculation of elastic alloy scattering rates presented in an earlier paper are also given. Elastic alloy disorder scattering is found to dominate over inelastic scattering, except for almost pure silicon \((x=0)\) or almost pure germanium \((x=1)\), where acoustic phonon scattering is predominant. The \( n \)-type carrier mobility, calculated from the total (elastic plus inelastic) scattering rate, using the Boltzmann transport equation in the relaxation time approximation, is in excellent agreement with experiments on bulk, unstrained alloys.

I. INTRODUCTION

SiGe has been studied for many years as an ideal, prototypical, binary semiconductor alloy.\(^1\) Recently, its use in complementary metal-oxide semiconductor (CMOS) technology has increased due to its versatility in heterostructure devices, where transport properties are of key importance.\(^2\) As alloying, strain engineering and quantum confinement change the electronic states and their coupling to the chemical or vibrational fluctuations in the active region of a device, different physical mechanisms of the carrier scattering (e.g., alloy disorder, interface roughness, intravalley or intervalley phonon scattering) may increase or decrease in importance. While carrier mobility measurements in bulk systems provide much information about scattering mechanisms, they do not always uniquely determine the separate contributions.\(^1\) Thus, it is of considerable practical and physical interest to be able to theoretically predict the charge transport properties of semiconductor devices from a knowledge of their atomic structure only. Ideally, we would like to be able to do so with a level of quantitative confidence comparable to that with which we can now calculate structural and vibrational properties of atomic-scale structures.

Our aim in this paper is to present general, first-principles electronic structure theory methods, by which carrier mobility can be calculated from a knowledge of atomic-scale structure only, without phenomenological input. We will restrict our applications here to those required to give a complete, first-principles calculation of carrier scattering in bulk SiGe alloys, but we expect that some of the techniques and scattering parameters for the SiGe system will be applicable, with some modification, in other contexts. In particular, the scattering parameters and deformation potentials may be of interest in the study of transport in devices.

Theoretical work on elastic carrier scattering due to disorder in binary alloys has advanced greatly since the early work of Nordheim.\(^3\) A notable example of these methods is the coherent potential approximation, or CPA, in which the scattering rates are calculated in terms of the scattering by individual alloy constituents.\(^4,5\) By and large, these developments have treated the interaction of individual atoms with the carrier states on a phenomenological basis.

The earliest theoretical study of the electronic transport properties of pure silicon or germanium concentrated on inelastic scattering by acoustic phonons, using measured or phenomenological values of the acoustic deformation potentials.\(^6\) \textit{Ab initio} calculations of physical properties, such as the acoustic\(^7,8\) and intervalley\(^9\) deformation potentials, required to find the carrier scattering, have been previously performed for Si and Ge, albeit using a model solid approach or with the Harris functional. The first \textit{ab initio} to calculate transport properties from \textit{ab initio} electronic structure theory obtained the elastic alloy scattering in SiGe, and included inelastic phonon scattering phenomenologically. Subsequently, this approach was also applied to find the hole mobility in SiGe\(^10\) and carrier mobilities in GeSn.\(^11\) More recently,\(^12\) a \textit{full ab initio} method has been applied to obtain electron-phonon relaxation times in GaAs and GaP. Earlier calculations performed with empirical methods\(^1,14–16\) had to rely on often inaccurate experimental data, and were unable to determine the relative strength of the different scattering mechanisms.

Before the work of Ref.\(^ 10\), alloy intervalley scattering had either been deemed negligible,\(^1\) or could not be distinguished from intravalley scattering.\(^14,16–19\) The relative strength of intra- and intervalley scattering is of particular importance in understanding mobility in strained SiGe alloys because strain lifts the degeneracy of the valleys and removes certain scattering channels (in particular, intervalley \( f \)-type scattering in Si-rich alloys and \( L-L \) scattering in Ge-rich alloys), which are available in the cubic system.

1098-0121/2008/78(3)/035202(14) 035202-1 ©2008 The American Physical Society
In this paper we calculate from first principles the $n$-type carrier scattering by phonons in an ideal, perfectly random SiGe alloy. To give a complete treatment of the carrier scattering in this system, we also present full details of the first-principles calculation of elastic alloy scattering, first given briefly in Ref. 10. Together, these provide a complete first-principles description of $n$-type carrier scattering in this alloy, which is in excellent agreement with available experimental data. The methods outlined here are not specialized for SiGe, but can readily be used to calculate carrier mobility for a range of conventional strained or unstrained semiconductor alloys.

An important contribution of this paper is the set of calculated parameters governing transport, which may be used in further phenomenological calculations. Readers interested in using these parameters should concentrate on Secs. VII A 2 and VII A 3, in which the value of the calculated intra- and intervalley electron-phonon coupling parameters, respectively, are presented. The remaining sections describe the method for calculating the parameters from first-principles electronic structure theory.

In Sec. II, we review the relevant aspects of the conduction bands of SiGe alloys and their calculation, using density functional theory (DFT) and the more accurate GW quasi-particle theory. We then derive in Sec. III a general expression for elastic alloy scattering in a weakly-scattering binary alloy, which is suitable for use in the context of first-principles supercell electronic structure methods. While it is well known that the DFT band structure does not necessarily reproduce the correct quasiparticle band structure, long-wavelength phonons, where the phonon wavelength is long compared to the variation in the phonon spectrum, and short-wavelength acoustic phonons, where the phonon wave vector dependence and demonstrate that the deformation potential approximation is accurate in treating intervalley acoustic scattering.

In Sec. V we give an expression for the total carrier mobility, calculated using the Boltzmann transport equation in the relaxation time approximation.

In Secs. VI and VII of the paper, we apply these methods to random SiGe alloys and calculate the parameters determining the inelastic intravalley deformation potential approximation. These phonons have short wave vectors and low frequencies and give rise to quasielastic intravalley scattering. We use a frozen phonon supercell approach to calculate the deformation potentials for long-wavelength acoustic phonons, which allows us to obtain their wave vector dependence and demonstrate that the deformation potential approximation is accurate in treating intervalley acoustic scattering.

In the second regime, the long-wavelength phonons are well represented in the average mass approximation, where all atomic masses are replaced by the average atomic mass, and the electron-phonon interaction is treated within the deformation potential approximation. These phonons have short wave vectors and low frequencies and give rise to quasielastic intravalley scattering. We use a frozen phonon supercell approach to calculate the deformation potentials for long-wavelength acoustic phonons, which allows us to obtain their wave vector dependence and demonstrate that the deformation potential approximation is accurate in treating intervalley acoustic scattering.

In Sec. V we give an expression for the total carrier mobility, calculated using the Boltzmann transport equation in the relaxation time approximation.

In Secs. VI and VII of the paper, we apply these methods to random SiGe alloys and calculate the parameters determining the inelastic intravalley deformation potentials, and compare them, where available, to previous theoretical and experimental results. Elastic alloy scattering parameters have been given in Ref. 10. We then calculate the $n$-type carrier scattering rate and find the carrier mobility.

Elastic alloy disorder scattering dominates over phonon scattering, except for almost pure silicon ($x \approx 0$) or almost pure germanium ($x \approx 1$). On the other hand, we find that considering alloy disorder explicitly in the calculation of the intervalley and optical phonon scattering makes very little difference, compared to an average mass treatment, in which alloy disorder is completely ignored.

II. CONDUCTION BAND MINIMA IN SiGe

Depending on alloy composition, the conduction band minimum in Si$_{1-x}$Ge$_x$ is either at the L-point or the $\Delta$-point, $k = \frac{2\pi}{a} (\xi, 0, 0)$, with $\xi = 0.83$; if the alloy contains less than 85% Ge, the conduction band minimum is at the $\Delta$ valley, otherwise it is at the L valley. Near Ge content $x = 0.85$, scattering between the nearly degenerate $\Delta$ and L valleys becomes important. The $\Delta$ band has six equivalent valleys in the [001], [00$\bar{1}$], [010], [01$\bar{0}$], [100], and [1$\bar{0}$0] crystallographic directions, while the L band has four equivalent valleys along the [111], [111], [1$\bar{1}$1], and [1$\bar{1}$1] directions (see Fig. 1). Two distinct parameters characterize $\Delta$ intervalley scattering: [001] $\rightarrow$ [00$\bar{1}$] is $g$-type and [001] $\rightarrow$ [100] is $f$-type. The intervalley scattering between the L valleys requires only one parameter, which we shall label $LL$. The conduction bands in the $\Delta$ and L valleys display a quadratic dispersion in $k$-vector near the band minimum at $k_n$:

$$E(k) = E(k_n) + \frac{\hbar^2 \Delta k^2}{2m_i} + \frac{\hbar^2 \Delta k^2}{2m_i},$$

where $\Delta k_i$ and $\Delta k_{i\perp}$ are the components of $k \cdot k_n$ parallel and perpendicular, respectively, to $k_n$. The surfaces of constant energy are ellipsoids of revolution, with the axis of revolution parallel to the direction of the valley, $k_n$, as shown in
FIRST-PRINCIPLES CALCULATION OF CARRIER...

...trons with different effective masses, $m_l^\alpha$ or $m_l^\beta$, depending on the direction of motion: the longitudinal mass $m_l$ for transport along the longitudinal axis direction, $k_\alpha$, and the transverse mass $m_t$ for transport along the transverse axes perpendicular to $k_\alpha$.

Calculated and experimental values of the effective masses are shown in Table I (details of the calculations are given below). Also shown are the calculated values of the lattice constants and energy differences between important symmetry points. The agreement generally between calculated and measured values is excellent, except for the values of the band gap $E_g$.

Throughout this work we have used the VCA for the calculation of various properties of the average alloy. In this approximation, the ionic potential of an alloy atom at Ge composition $x$ is built from the average of the ionic potentials of the alloy constituents, as

$$V_{x}^{\text{VCA}} = xV_{\text{Ge}} + (1 - x)V_{\text{Si}}.$$  \hfill (2)

The VCA proves very useful whenever the properties calculated do not depend strongly on alloy disorder.

### III. ELASTIC ALLOY SCATTERING

In this section we derive an expression for the alloy scattering rate from Fermi’s second golden rule and the $T$-matrix formalism. If we consider two ideal crystal states, $\psi_k$ and $\psi_{k'}$ of equal energy, the scattering rate between them will be proportional to the $T$-matrix element squared,

$$R(E(k_\alpha)) = \frac{2\pi}{\hbar} \sum \beta \int \frac{d^3k_\beta}{(2\pi)^3} |\langle \psi_{k_\beta} | T | \psi_{k_\alpha} \rangle|^2 \times \delta(E(k_\alpha) - E(k_\beta)).$$  \hfill (3)

where $\Omega$ is the volume of the system, and $\beta$ labels the valley into which scattering occurs. We now wish to find the dependence of Eq. (3) on the alloy composition. SiGe can be seen as a random substitutional alloy with two building blocks: one corresponding to Ge sites, with probability $x$, and one to Si sites, with probability $(1-x)$. We will make three assumptions about the alloy, which we shall test later: (i) that Si and Ge are relatively weak scatterers in the alloy, thus allowing us to consider that each site scatters the carriers independently; (ii) that the alloy is completely random, and there is no correlation between the atomic species on different sites; and (iii) that the average of the scattering matrix $\tilde{T}(k,k')$ is 0. The last assumption is equivalent to the CPA, where the average crystal does not scatter.
The scattering amplitude for each site $i$ is given by
\[ T_i(k, k') = \langle \psi_i | T | \psi_i \rangle = \langle \psi_i | V_i | \phi_i \rangle, \]
where $V_i$ is the change in potential due to an impurity at site $i$. The total scattering amplitude is thus,
\[ T(k, k') = \sum_{i=1}^{N} T_i(k, k'), \]
with $N$ as the total number of sites. Let $T_i(k, k') = T_i(k, k') + \delta T_i(k, k')$, where $T_i(k, k')$ is the average of $T_i(k, k')$ over the entire system, and $\delta T_i(k, k')$ is the variation from the average. The average of the square of the scattering amplitude over the ensemble of configurations of the random alloy is then given by
\[ \langle |T(k, k')|^2 \rangle = \sum_{i=1}^{N} \sum_{j=1}^{N} \langle \delta T_i^*(k, k') \delta T_j(k, k') \rangle, \]
in which we have used the assumption that the average $T = 0$. The quantity $\langle \delta T_i^*(k, k') \delta T_j(k, k') \rangle$ is the covariance between $T_i$ and $T_j$, which vanishes unless $j = i$, since we have assumed that the contribution from different sites are statistically independent. As a result, the average of the square of the total scattering amplitude is
\[ \langle |T(k, k')|^2 \rangle = N \langle |\delta T_i^*(k, k') \delta T_i(k, k')|^2 \rangle, \]
with $\langle |\delta T_i^*(k, k') \delta T_i(k, k')|^2 \rangle$ as the variance of $T_i(k, k')$, which is the same for all sites.

In SiGe, the sites are either occupied by Si or Ge, so that $T_i$ is equal to $T_{Si} = \langle \phi_i | V_{Si} | \phi_i \rangle$, with $A = Si$ or Ge. The variance of this binary substitutional alloy can then be expressed in terms of the scattering produced by the substitution of an atom of one type for another:
\[ \langle |\delta T_i^*(k, k') \delta T_i(k, k')|^2 \rangle = x(1-x)|T_{Si} - T_{Ge}|^2. \]
Each site $i$ in a SiGe alloy occupies a volume equal to $\frac{1}{8}$, that is, half of the volume of an fcc primitive cell, with $a_0$ as the lattice constant. The volume of the system is then $\Omega = N a_0^3$, and the scattering rate becomes
\[ R(E(k_0)) = \frac{2\pi}{\hbar} x(1-x) \frac{a_0^3}{8} \int \frac{d^3k'}{(2\pi)^3} \langle V_{Ge} \rangle \delta(E(k_0) - E(k_0')) \]
where we have defined
\[ \langle V_{Ge} \rangle = N(T_{Si}^B - T_{Ge}^B) = N(\psi_a | V_{Si} | \phi_b) - N(\psi_a | V_{Ge} | \phi_b). \]

In the last equation we have removed the reference to the wave-vector $k$, since the matrix elements do not depend strongly on them when $k$ is in valley $\alpha$ and $k'$ is in valley $\beta$. The reason for this is that the potential is short-ranged in comparison to the wavelength of the carriers. The potential $V_{\alpha}$ is that of a perturbation caused by the substitution of an atom of the periodic host by a type-$A$ atom, and $\phi$ is the exact eigenstate in the presence of the perturbing potential that satisfies the boundary condition $\phi_{\alpha}(r) \to \phi_{\beta}(r)$, for $|r|$ far away from the type-$A$ atom. We can replace the integral over $k'_{\beta}$ in Eq. (9) by one over the energy $E(k')$, yielding
\[ R(E) = \frac{2\pi}{\hbar} x(1-x) \frac{a_0^3}{8} \sum_{\beta} \langle V_{Ge} \rangle^2 \rho_{\beta}(E), \]
where $\rho_{\beta}(E)$ is the density of states (DOS) per spin per unit volume in the final valley $\beta$ at the carrier energy $E$. Both intravalley ($\beta = \alpha$) and intervalley ($\beta \neq \alpha$) terms are included in the total scattering rate.

The periodic host is represented in the VCA. We calculate the potential $V_A$ by placing one $A$-type atom as a substitutional defect in a supercell of $N-1$ VCA host atoms. DFT is used to compute the single-particle electronic states $|\psi_i\rangle$ and to relax the atomic structure around the defect atom in the supercell. The CPA correction to the VCA band dispersion is calculated, and found to be small.\cite{26}

Note that the use of the wave function $\phi$ is important in correctly calculating the scattering matrix element. The simple form of first Born approximation, where $\phi$ is replaced by the undistorted Bloch wave function $\psi$, will not apply because the Si and Ge potentials are substantially different from the average host atomic potential near the ion and, as a result, the electronic wave function $\phi$ is quite different from $\psi$ there. Moreover, the relaxation of the shells of atoms around the Si or Ge atom also distorts the wave function $\phi$, compared with the Bloch state.

We use the ellipsoidal approximation in Eq. (1) to obtain the density of states per spin in valley $\beta$ at the carrier energy $E$:
\[ \rho_{\beta}(E) = \sqrt{\frac{m_{\beta}^T m_T^\beta \left(E - E_{\beta}^c\right)}{2\pi\hbar^3}} \Theta(E - E_{\beta}^c), \]
where $\Theta(a)$ is a unit step function (0 if $a < 0$, 1 otherwise), $E_{\beta}^c$ is the conduction band minimum energy, and $m_T^\beta$ and $m_{\beta}^T$ are the longitudinal and transverse effective masses, respectively, for valley $\beta$.

Two technical complications arise in finding the appropriate matrix element $\langle \psi_{\alpha} | \Delta V | \phi_{\beta} \rangle$ from a finite supercell: (a) The degenerate or nearly degenerate band states in the host supercell are mixed as a result of breaking the translational symmetry of the host by the $A$-type defect. Therefore, no eigenstate of the Hamiltonian satisfies the boundary condition $\phi_{\alpha}(r) = \psi_{\beta}(r)$ in the limit of $|r|$ far away from the $A$-type atom. This problem is solved by defining a state as the linear combination of the nearly degenerate energy eigenstates $|\phi_{\alpha}\rangle$ which has the largest overlap with the state $|\phi_{\beta}\rangle$, as explained in Ref. 10. \(b\) In a supercell, the zero of the potential is arbitrary and a physically well-defined way must be developed to compare the potential in the supercell with $N$ host atoms and that with one type-$A$ atom and $N-1$ host atoms.

A. Mixing of nearly degenerate states

The method for including the mixing of nearly degenerate states has been treated in Ref. 10. Here we present how to
obtain the scattering parameters directly from the band-
structure calculations. It should be remarked that the choice of $M$ in Eqs. (3) and (5) of Ref. 10 depends on the particular system under consideration, and is affected by the size of the supercell and by which bands fold into the $\Gamma$ point in the Brillouin zone of the supercell. In our case, for instance, there is a range in composition where the $\Delta$, $L$ and $\Gamma$ valleys cross, and are almost degenerate in energy, but well separated from other bands. Therefore, in the 64-atom supercell case, we consider $M=17$ to include the 6 $X$ eigenstates, the 6 $\Delta$-points, $k=\frac{2\pi}{a}\xi(x,0,0)$, etc., with $\xi=\frac{1}{2}$, the 4 $L$ states, and 1 $\Gamma$ state. The 128-atom supercell will require an $M$
=49, since there are other bands folding into the $\Gamma$ point with energies close to the conduction band minimum.

However, we should note that too big an $M$ would recover the first Born approximation $|\phi_{\beta}|^2=|\phi_{\alpha}|^2$. As we commented above, the correct state $\phi_{\beta}$ is distorted near the defect atom. This is not substantially altered by mixing the $M$ low-lying conduction band states since each of these states will exhibit a similar distortion near the defect atom. However, if $M$ is large enough to include all bands, then $|\phi_{\beta}|$ in Eq. (3) of Ref. 10 becomes equal to $|\phi_{\alpha}|$.

Depending on the symmetry of the valley, the eigenvalues of the matrix in Eq. (4) of Ref. 10 will split in different ways. From these splittings we can obtain the inter- and intravalley scattering parameters for the $\Delta$ and $L$ valleys. If we diagonalize the part of the matrix belonging to the $\Delta$ valley, the six originally degenerate eigenvalues split into threefold, twofold, and nondegenerate eigenvalues. From these, the scattering parameters can be obtained as follows:

$$V_{\Delta} = \frac{1}{6}(E_1 + 2E_2 + 3E_3),$$

$$V_{\Delta^2} = \frac{1}{6}(E_1 + 2E_2 - 3E_3),$$

$$V_{\Delta^3} = \frac{1}{6}(E_1 - E_2),$$

where $E_i$ is the $i$-fold degenerate eigenvalue. Likewise, the four degenerate eigenvalues from the $L$ valley split into a threefold and a nondegenerate eigenvalue. The scattering parameters are obtained from

$$V_{L} = \frac{1}{4}(E_1 + 3E_3),$$

$$V_{L^2} = \frac{1}{4}(E_1 - E_3).$$

The parameters for the $\Delta-L$ scattering are obtained from the matrix elements between these two valleys, that is, from the elements in Eq. (4) of Ref. 10 in which $\alpha$ belongs to the $\Delta$ valley and $\beta$ to the $L$ valley, in the following way:

$$V_{\Delta L} = \sqrt{\frac{1}{24} \sum_{\alpha \in \Delta, \beta \in L} \langle \psi_{\alpha}|dV^\text{red}|\psi_{\beta}\rangle^2}.$$

**B. Potential zero shift**

The expression for the scattering matrix $T_{ij}$ in Eq. (4) assumes that the perturbing potential $V_i$ due to the substitution of atom $A$ at site $i$, tends to zero at large distance from site $i$. In a supercell calculation, the zero of potential energy is not physically well defined. In practice, the average of the local potential $V_{\text{loc}}(r)$ over the supercell is usually set to zero. However, in order to calculate properly the scattering $T$-matrix from Eq. (4), we must shift the zero of the local potential in the lattice containing a type-$A$ atom, so that far from this atom it matches the corresponding potential in the periodic VCA host lattice.

To do this, we define the difference potential, $\Delta V^\text{loc}_{\text{loc}}(r_i) = V^\text{loc}_{\text{loc}}(r_i) - V^\text{VCA}_{\text{loc}}(r_i)$, on the fast-Fourier-transform grid points $r_i$ in an $N$-atom supercell. Here, $V^\text{loc}_{\text{loc}}(r)$ is the local potential in the supercell containing one type-$A$ atom (at the origin) and $N-1$ VCA atoms, and $V^\text{VCA}_{\text{loc}}(r)$ is the potential in a supercell of the same dimensions, containing $N$ VCA atoms in a perfect diamond lattice. We then define the average potential difference at distances greater than $r_a$ as

$$\langle \Delta V_{\text{loc}}(r_a) \rangle = \frac{1}{N_{\text{grid}}(r_a)} \sum_{|r_i| > r_a} \Delta V^\text{loc}_{\text{loc}}(r_i),$$

where $N_{\text{grid}}(r_a)$ is the number of grid points for which $|r_i| > r_a$ (Note that the distance $|r_i|$, defined here, is the distance to the nearest image of atom $A$ in the periodically repeated system defined by the supercell; alternatively, we assume that grid points $r_i$ lie within the Wigner-Seitz cell for the supercell.). For supercells with 16 atoms or more, we find that $\langle \Delta V_{\text{loc}}(r_a) \rangle$ converges to a fairly constant value for large $r_a$, less than the Wigner-Seitz radius. This value is the required shift of the potential, to be subtracted from electronic eigenvalues for the system with one type-$A$ atom, before the calculation of the reduced Hamiltonian in Eq. (5) of Ref. 10. Note that nonlocal parts of the atomic pseudopotentials are short-ranged and do not contribute to the average potential shift at large distance from atom $A$. Note also that the inter-valley ($\alpha \neq \beta$) scattering parameters obtained in Eq. (4) of Ref. 10 from the reduced Hamiltonian, do not depend on the shift of the average potential in the supercell.

Figure 2 shows $\langle \Delta V_{\text{loc}}(r_a) \rangle$ as a function of $r_a$ for a Si
atom or a Ge atom in a 64-atom supercell, where the VCA host has composition, $x=0.5$. By construction, $\langle \Delta V_{\text{loc}}(r_a) \rangle = 0$ at $r_a=0$. All atomic positions have been relaxed in the supercell containing the Si (or Ge) atom to minimize the total energy of the system and the oscillations in $\langle \Delta V_{\text{loc}}(r_a) \rangle$ for $r_a>2$ Å are largely associated with the resulting relaxation of atoms from their ideal diamond lattice positions.

IV. INELASTIC SCATTERING BY PHONONS

A. Alloy phonon modes

In this section, we outline the methods used to calculate the phonon modes of the random alloy. We use density functional theory to calculate the forces in the alloy. The interatomic force constants in silicon and germanium are very similar and the differences in vibrational spectra arise principally from the difference in the atomic masses of silicon ($m_{\text{Si}}$) and germanium ($m_{\text{Ge}}$). (We will directly test this approximation for SiGe in Sec. VII A 2, below.) Following the approach of de Gironcoli and Baroni,23 we will approximate the interatomic forces in the random alloy within the virtual crystal approximation. Using the random mass approximation, we then find the dynamical matrix of the alloy for an explicit random distribution of atomic masses.

We represent the short-wavelength and optical phonon spectrum and electron-phonon coupling in the alloy with that of a large supercell, containing $N_S$ primitive diamond (fcc, two-atom) unit cells, with periodic boundary conditions. The supercell is a parallelepiped region, $[r=\eta_1A_1+\eta_2A_2+\eta_3A_3|0 \leq \eta_i < 1]$, with sides defined by the vectors $A_1$, $A_2$, and $A_3$. Germanium and silicon atoms are randomly distributed, each diamond lattice site being occupied by germanium or silicon, with probability $x$, or silicon, with probability $1-x$. In the fcc Brillouin zone, there are $N_S$ wave vectors $q$ that satisfy periodic boundary conditions on the supercell; i.e., $\exp[iq \cdot A_j]=1$, for $j=1,3$.

Thus, we calculate the interatomic force constants for the VCA periodic diamond structure, in which every atom has the ionic pseudopotential $V_{\text{SC}}^{\text{VCA}}$, defined in Sec. II. For each wave vector $q$, which satisfies periodic boundary conditions on the supercell, we calculate the $6 \times 6$ force constant matrix $\tilde{C}_{\tau,\alpha,\tau',\alpha'}(q)$ for the VCA diamond structure, where $\tau$ and $\tau'$ index the atom within the fcc unit cell ($\tau=1,2$) and $\alpha$ and $\alpha'$ label the Cartesian direction of motion ($\alpha=1,3$). This is calculated using the density functional perturbation theory method, as specified in Gonze and Lee.27

For an ordered diamond lattice, in which every atom has mass $m$, the eigenvalues of the dynamical matrix, $D(q) = \tilde{C}(q)/m$, are the square of the phonon frequencies $\omega_{\tau,\alpha}^2$, $\lambda = 1,6$, for momentum $q$. The eigenvectors $u_{\tau,\alpha}(\lambda, q)$ of $D(q)$ give the displacement $u_{\tau,\alpha}(\lambda, q) \exp[iq \cdot R]/\sqrt{m}$ of atom $\tau$ within the fcc unit cell at position $R$ for the $\lambda$ branch phonon mode of momentum $q$. In an infinite, ordered diamond lattice, the interatomic force constants between atom $\tau$ in the unit cell at $R_a$ and atom $\tau'$ in the unit cell at $R_b$ are given by

$$
\frac{\partial^2 E}{\partial r_{\tau,\alpha} \partial r_{\tau',\alpha'}} = C_{\tau,\alpha,\tau',\alpha'}(R_b - R_a)
$$

$$
= \frac{V_{\text{cell}}}{(2\pi)^3} \int_{\text{BZ}} \tilde{C}_{\tau,\alpha,\tau',\alpha'}(q) \times \exp[-iq \cdot (R_b - R_a)] d^3q,
$$

where $E$ is the total energy of the lattice, $r_{\tau}'$ is the displacement from equilibrium of atom $\tau$ in the unit cell at $R$, $V_{\text{cell}}$ is the volume of the diamond primitive unit cell, and the integral, $\int_{\text{BZ}} d^3q$, is over all wave vectors in the fcc Brillouin zone.

To find the vibration modes of the supercell, allowing for the explicit random distribution of silicon and germanium atoms, let us label the $2N_S$ atoms in the supercell with the index $\kappa$. For each atom, let $R_{\kappa}$ be the position of the diamond unit cell in which it is located and $\tau_{\kappa}$ be its index within that cell. Thus, $\kappa$ can be considered as a composite index $(\tau_\kappa, R_\kappa)$ and summations over $\kappa$ can be considered as a sum over the $N_S$ values of $R$ in the supercell and over $\tau = 1,2$. The mass of atom $\kappa$ is $m_\kappa$, which is the mass of either a silicon atom or a germanium atom. In the supercell with periodic boundary conditions, the interatomic force matrix is given by

$$
C^{\text{SC}}_{\kappa,\alpha,\kappa',\alpha'} = \frac{1}{N_S} \sum_{q} \tilde{C}_{\tau,\alpha,\tau',\alpha'}(q) \exp[-iq \cdot (R_\kappa - R_{\kappa'})],
$$

where the summation $\sum_{q}$ is over the $N_S$ wave vectors $q$ that satisfy periodic boundary conditions on the supercell. The dynamical matrix for the supercell with periodic boundary conditions is then

$$
D^{\text{SC}}_{\kappa,\alpha,\kappa',\alpha'} = \frac{1}{\sqrt{m_{\kappa}}} C^{\text{SC}}_{\kappa,\alpha,\kappa',\alpha'}. \quad (22)
$$

Diagonalization of $D^{\text{SC}}$ yields eigenvalues $\omega_{\kappa}^2$ and normalized eigenvectors $u_{l,\kappa,\alpha'}$ for $l=1,6N_S$. The vibrational frequencies of the supercell are $\omega_{l}$ and the displacement of atom $\kappa$ in mode $l$ is $u_{l,\kappa,\alpha'}/\sqrt{m_{\kappa}}$.

For the very long-wavelength acoustic modes, the explicit distribution of silicon and germanium atoms has relatively little effect on the modes. In this limit, we can, not only treat the forces between atoms within the VCA, but also make the “average mass” approximation, viz. that each atom has a mass, $m = x m_{\text{Si}} + (1-x) m_{\text{Ge}}$, equal to the average atomic mass in the alloy. Thus, the long-wavelength acoustic modes can be well represented by the corresponding modes of a perfect diamond lattice (without disorder) and intravalley electron scattering by acoustic phonons is well described within this picture of the alloy.

Due to the restriction of periodic boundary conditions on the supercell, the low-frequency, long-wavelength modes relevant for acoustic intravalley scattering are not well represented, even in supercells of several hundred atoms, which are quite adequate to represent the high-frequency phonon modes. For this reason, we calculate the acoustic intravalley scattering using the analytical approach of Herring and
Vogt, which is based on the deformation potential model of coupling between electrons and long-wavelength acoustic modes. We calculate the deformation potential parameters from first principles, using a “frozen phonon” method (see Sec. IV C, below). In addition, this method allows us to directly verify the applicability of the deformation potential model for the phonon wave vectors relevant in intravalley carrier scattering.

**B. Intervalley and optical phonon scattering**

We now consider the scattering of carriers due to their coupling to the phonons of the alloy. The scattering rate due to absorption and emission of a phonon of energy \( \hbar \omega_j \) is given by

\[
R_{i \to f} = \frac{2 \pi}{\hbar} \sum_{k, \alpha \lambda = \pm} |f(V_{\text{el-ph}})\delta(E_f - E_i)|^2,
\]

where \( \pm \) indicates sum over emission and absorption processes, \( f(V) \) is the matrix element of the electronic-phonon interaction between initial and final states, \( |\pm \rangle = |n(k) \rangle \otimes |n_j \rangle \) and \( |\pm \rangle = |n \pm k \rangle \otimes |n_{i \lambda} \rangle \), respectively. Here, \( |n(k) \rangle \) is the Bloch electronic state of momentum \( k \) in band \( n \) for the VCA potential and \( |n_j \rangle \) is the vibrational state of the alloy with \( n_{i \lambda} \) phonons in mode \( l \). The energy of the initial state is

\[
E_i = \epsilon_{nk} + \sum_{l'} n_{l'} \hbar \omega_j,
\]

and that of the final state is

\[
E_f = \epsilon_{nk'} + \sum_{l'} n_{l'} \hbar \omega_j \pm \hbar \omega_j.
\]

At temperature \( T \), the average value of \( n_j \) is given by the Bose-Einstein distribution,

\[
n_j = n(\hbar \omega_j) = \frac{e^{\hbar \omega_j/k_B T} - 1}{e^{\hbar \omega_j/k_B T} + 1},
\]

where \( k_B \) is the Boltzmann constant. The electron-phonon interaction in the system of \( N_s \) diamond unit cells is

\[
V_{\text{el-ph}} = \sum_{l = 1}^{6N_s} \sum_{k = 1}^{2N_s} \sqrt{\frac{\hbar}{2m_{nl}}} (a_l \mathbf{u}_{l,k} + a_l^i \mathbf{u}_{l,k}^*) \cdot \frac{\partial V_k}{\partial \mathbf{r}_k},
\]

where \( a_l \) and \( a_l^i \) are the phonon destruction and creation operators, respectively, for mode \( l \) and \( \frac{\partial V_k}{\partial \mathbf{r}_k} \) is the derivative of the electronic potential with respect to the displacement of ion \( k \).

Electronic disorder is weak in SiGe and we calculate \( \frac{\partial V_k}{\partial \mathbf{r}_k} \) using the VCA for the ionic potential. Writing the composite index \( k \) in the form \( \{ \mathbf{r}, R \} \), as defined in Sec. IV A, and bearing in mind that the electronic Bloch state \( \psi_{nk}(\mathbf{r}) \), which is normalized in the supercell region of \( N_s \) diamond unit cells, satisfies the equation

\[
\psi_{nk}(\mathbf{r} + \mathbf{R}) = e^{i \mathbf{k} \cdot \mathbf{R}} \psi_{nk}(\mathbf{r}),
\]

the electronic matrix element can be written as

\[
\langle mk' | \frac{\partial V_k}{\partial \mathbf{r}_k} | nk \rangle = e^{-i (k' - k) \cdot \mathbf{R}} \langle mk' | \frac{\partial V_k}{\partial \mathbf{r}_k} | nk \rangle = e^{-i \Delta k \cdot \mathbf{R}} \frac{1}{N_s} \mathbf{H}_{k'km}^\alpha \mathbf{H}_{k'km}^\alpha \mathbf{H}_{k'km}^\alpha,
\]

where \( \Delta k = k' - k \) is the change in momentum of the electron state in the scattering process. Here, \( \mathbf{H}_{k'km}^\alpha \) is a Cartesian vector, whose \( \alpha \) component \( \mathbf{H}_{k'km}^\alpha \) is the matrix element of the change in the potential due to the displacement of atom \( \tau \) in direction \( \alpha \) in the diamond unit cell at the origin, \( \mathbf{R} = 0 \). This matrix element is the first-order Hamiltonian in Eq. (61) of Ref. 29, and can be obtained directly from density functional perturbation theory, using the VCA ionic potential.

The phonon absorption term (containing \( a_i \)) in the electron-phonon interaction can then be formulated as

\[
\sqrt{\frac{\hbar}{2 \omega_j}} \sum_{m = 1}^{2N_s} \mathbf{u}_{m,k} \cdot \frac{\partial V_k}{\partial \mathbf{r}_k} |n_k\rangle = \frac{1}{\sqrt{N_s}} \sqrt{\frac{\hbar}{2m\omega_j}} \sum_{m = 1}^{2N_s} \tilde{X}_{i,l}(\Delta k) \cdot \mathbf{H}_{k'km}^\alpha,
\]

where we have defined

\[
\tilde{X}_{i,l}(\Delta k) = \sum_{\mathbf{R}} \mathbf{m} \mathbf{u}_{m,k}^\alpha \mathbf{H}_{k'km}^\alpha.
\]

with \( \mathbf{m} \) as the average atomic mass, and \( \mathbf{R} \) summed over the \( N_s \) primitive cells in the supercell. Notice that if there was no disorder and the phonon momentum \( \mathbf{q} \) was well defined for each mode \( l \), \( \tilde{X}_{i,l}(\Delta k) = 0 \) unless \( \Delta k = \mathbf{q} \). In the disordered alloy, \( \tilde{X}_{i,l}(\Delta k) \) gives the spatial Fourier transform of the atomic displacements of atom \( \tau \) in the unit cell for phonon mode \( l \). Defining

\[
R_{m,n}^k(E) = \sum_{l = 1}^{6N_s} \sum_{m = 1}^{2N_s} \tilde{X}_{i,l}(k' - k) \cdot \mathbf{H}_{k'km}^\alpha |\delta(E - \hbar \omega_j)|,
\]

the carrier scattering rate from \( |n(k) \rangle \) into all \( |n(k') \rangle \) by phonon absorption is

\[
R_{m,n}^k(\epsilon_{nk}) = 2 \pi \sum_{m, k'} \frac{\hbar \mathbf{H}_{m,n}^k(\epsilon_{nk} - \epsilon_{nk'}) \times n(\epsilon_{nk'} - \epsilon_{nk}) \Theta(\epsilon_{nk'} - \epsilon_{nk})}{2m(\epsilon_{nk'} - \epsilon_{nk})},
\]

where \( \Theta(a) \) is a unit step function (0 if \( a < 0 \), 1 otherwise). The scattering rate by phonon emission is

\[
R_{m,n}^k(\epsilon_{nk}) = 2 \pi \sum_{m, k'} \frac{\hbar \mathbf{H}_{m,n}^k(\epsilon_{nk} - \epsilon_{nk'}) \times n(\epsilon_{nk} - \epsilon_{nk'}) \Theta(\epsilon_{nk} - \epsilon_{nk})}{2m(\epsilon_{nk} - \epsilon_{nk})},
\]

The total scattering rate is the sum of phonon absorption and emission rates:

\[
R_{m,n}^k(\epsilon_{nk}) = R_{m,n}^k(\epsilon_{nk}) + R_{m,n}^k(\epsilon_{nk}).
\]
For optical and intervalley scattering, $P_{n,m}^{k', k}(E)$ has a weak dependence on $k'$ and $k$ near the conduction band valley minima, where the carriers are concentrated. Therefore, in calculating the optical phonon and intervalley scattering, we will approximate

$$P_{n,m}^{k', k}(E) \approx P_{n,m}^{\beta \alpha}(E),$$

(36)

where $k$ is in the $\alpha$ valley of band $n$ and $k'$ is in the $\beta$ valley of band $m$. Replacing $\frac{N}{V} \sum_{k} \rightarrow \frac{V_{\text{cell}}}{(2\pi)^3} \int d^3k$, where $V_{\text{cell}}$ is the volume of a primitive diamond unit cell, and using the parabolic approximation given in Eq. (12) for the density of states in valley $\beta$, the scattering rate into valley $\beta$ for carriers of energy $E$ in valley $\alpha$ due to phonon absorption is

$$R_{\alpha \rightarrow \beta}(E) = \frac{V_{\text{cell}} \sqrt{(m_f^\beta m_i^\beta)}}{\hbar^2 / 2 \pi m} \times \int_{E}^{\infty} dE' \frac{\sqrt{E' - E} e^{i\phi(E')}(E' - E)}{E' - E} n(E' - E).$$

(37)

Similarly, the scattering rate into valley $\beta$ for carriers of energy $E$ in valley $\alpha$ due to phonon emission is

$$R_{\alpha \rightarrow \beta}^*(E) = \frac{V_{\text{cell}} \sqrt{(m_f^\beta m_i^\beta)}}{\hbar^2 / 2 \pi m} \times \int_{E}^{\infty} dE' \frac{\sqrt{E' - E} e^{i\phi(E')}(E' - E)}{E' - E} [n(E - E') + 1].$$

(38)

C. Intravalley acoustic scattering

We calculate the acoustic phonon contribution to intravalley carrier scattering, following the deformation potential theory approach of Herring and Vogl, as outlined in Fischetti and Laux. In this section, we describe the calculation of the deformation potentials needed to compute the scattering of acoustic phonons in the $\Delta$ and $L$ valleys, using a frozen phonon approach. We do not use the density functional perturbation theory approach of Ref. 27 because we find numerical instability in some of the parameters calculated, resulting in an extreme sensitivity to Brillouin zone sampling, for very long wavelength perturbations.

We need two deformation potentials for each valley in question: $\Xi_{d}$, the dilation deformation potential, and $\Xi_{u}$, the uniaxial deformation potential. In the deformation potential approach, the effect of a low-wavelength acoustic phonon on the states in valley $\alpha$ is assumed to be equivalent to a slowly-varying potential,

$$V_{\alpha}(r) = \Xi_{d}^{\alpha} Tr[\varepsilon(r)] + \Xi_{u}^{\alpha} (\hat{k}_{\alpha} \cdot \varepsilon(r) \cdot \hat{k}_{\alpha}),$$

(39)

where $\varepsilon(r)$ is the local strain tensor at $r$ and $\hat{k}_{\alpha}$ is a unit vector parallel to the $k$-vector of valley $\alpha$. The strain tensor is obtained by

$$\varepsilon_{ij}(r) = \frac{1}{2} \left( \frac{\partial \delta R_{ij}}{\partial r_{j}} + \frac{\partial \delta R_{ij}}{\partial r_{j}} \right),$$

(40)

where $\delta R_{ij}$ is the $i$th Cartesian component of the atomic displacement vector at $r$.

For the $\Delta$ valley along the $x$ direction, $\hat{k}_{\alpha}=(100)$ and for the $L$ valley along the $\{111\}$ direction, $\hat{k}_{\alpha}=(111)/\sqrt{3}$. Taking displacement of the atoms due to a phonon of momentum $q$ and frequency $\omega$ as

$$\delta R(r) = \delta R_0 \sin(q \cdot r - \omega t),$$

(41)

we find that the matrix element (at $t=0$) coupling electron states $|k\rangle$ and $|k'\rangle$, each in valley $\alpha$, is

$$H_{k'k} = \langle k' | V^\alpha(r) | k \rangle = \frac{1}{2} \left( \Xi_{d} \delta R_{0} \cdot q + \Xi_{u} (\hat{k}_{\alpha} \cdot \delta R_{0} \cdot q \cdot \hat{k}_{\alpha}) \right) \times [\delta_{k-k',q} + \delta_{k-k',q}] = \delta_{k-k',q} = \delta_{k-k',q}.$$

(42)

For longitudinal phonons, we have $\delta R_{0} \parallel q$, and for transverse phonons, $\delta R_{0} \perp q$.

If the states, $|k \rangle$ and $|k+q \rangle$, are degenerate in energy for $\delta R_{0}=0$, then, for small $\delta R_{0}$ and $q$, the phonon causes an energy splitting of these states,

$$\delta E = 2 |H_{k+q,k}| = C q \delta R_{0},$$

(43)

where the constant $C$ is determined by the phonon strain tensor and the acoustic deformation potentials. The sign of $H_{k+q,k}$ is obtained from the matrix element

$$M_{k,k+q} = \langle k | \psi_{k} \langle \psi_{k+q} | k + q \rangle - \langle k | \psi_{k} \langle \psi_{k} | k + q \rangle,$$

(44)

where $|\psi_{k} \rangle$ and $|\psi_{k} \rangle$ are the wave functions corresponding to the upper and lower eigenvalues resulting from the splitting due to the frozen phonon, respectively. In Table II, we give phonon directions and polarizations which allow us to calculate deformation potentials for the $\Delta$ and $L$ valleys, along with the associated values of $C$ in Eq. (43).

We calculate this splitting directly in DFT, using elongated supercells, as follows: We take phonon wave vectors $q = \frac{2\pi}{N_{\alpha}} (0,1,0)$ along the [010] direction and $q = \frac{2\pi}{N_{\alpha}} (0, -1,1)$ along the [011] direction, where $N$ is an integer and $d_{0}$ is the cubic lattice constant. For the $q$ in the [010] direction, the transverse mode atomic displacement is in the [001] direc-
tion. For a given phonon wave vector \( \mathbf{q} \), we choose the smallest supercell in which \( \mathbf{q} \) is compatible with periodic boundary conditions. Defining the primitive diamond Bravais lattice basis vectors,

\[
\mathbf{a}_1 = \left( \frac{1}{2}, \frac{1}{2}, 0 \right) a_0, \\
\mathbf{a}_2 = \left( \frac{1}{2}, 0, \frac{1}{2} \right) a_0, \\
\mathbf{a}_3 = (1,0,0) a_0,
\]

we use a supercell with basis vectors, \( \mathbf{A}_1 = \mathbf{a}_1, \mathbf{A}_2 = \mathbf{a}_2, \mathbf{A}_3 = \mathbf{a}_3 \), for the phonon with \( \mathbf{q} = \frac{2\pi}{\mathbf{a}_0} (0,1,0) \) and a supercell with \( \mathbf{A}_1 = \mathbf{a}_1, \mathbf{A}_2 = \mathbf{a}_2, \mathbf{A}_3 = \mathbf{a}_3 \) for \( \mathbf{q} = \frac{2\pi}{\mathbf{a}_0} (0,-1,1) \). Atomic displacements specified by the acoustic phonon in Eq. (41) (for \( t=0 \)) are made from the ideal diamond lattice positions within the supercell and the self-consistent DFT electronic potential is calculated. If \( \mathbf{k}_a \) is the Bloch momentum of the valley minimum, then we calculate the band energies in the supercell for Bloch momentum \( \mathbf{k} = \mathbf{k}_a - \mathbf{q}/2 \) and find the splitting \( \delta E \) between the eigenstates, \( \left( \mathbf{k}_a + \mathbf{q}/2 \right) \) and \( \left( \mathbf{k}_a - \mathbf{q}/2 \right) \). In these calculations, we use the VCA potential \( V_N^{\text{VCA}} \) for all atoms in the supercell.

Since there are two atoms in the diamond unit cell (at equilibrium positions, \( r_1, \tau = 1,2 \)), then the pure acoustic displacement, \( \mathbf{u}_{ac}^\gamma = \sqrt{m} \mathbf{R}_0 \sin[\mathbf{q} \cdot (\mathbf{R} + \mathbf{r}_1)] \), and the pure optical displacement, \( \mathbf{u}_{op}^\gamma = (-1)^\gamma \sqrt{m} \mathbf{R}_0 \sin[\mathbf{q} \cdot (\mathbf{R} + \mathbf{r}_1)] \), are coupled for a general phonon wave vector and polarization, and the low-frequency (acoustic) vibrational mode is a mixture of both. Thus, in general we need to find the acoustic and optical components of the restoring forces on the atoms in the unit cell for both optical and acoustic frozen phonon displacements. Diagonalizing the resulting \( 2 \times 2 \) dynamical matrix, we obtain the correct mixture of the optical and acoustic displacements in the acoustic mode (and in the optical mode).

We note that, for the high-symmetry phonons considered here, the phonons are either pure longitudinal or pure transverse, so that the full \( 6 \times 6 \) dynamical matrix \( \mathbf{D}(\mathbf{q}) \) does not need to be solved. Moreover, for \( \mathbf{q} = (0\bar{1}1) \), the optical and acoustic displacements completely decouple by symmetry. The deformation potentials for the \( \Delta \) valley are insensitive, by symmetry, to the mixture of optical displacements in the acoustic mode, but those of the \( L \) valley are quite sensitive. We note that an admixture of the optical mode in an infinite wavelength acoustic phonon is equivalent to a change in the equilibrium internal atomic displacement parameter for a strained crystal. The sensitivity of the \( L \) valley electronic levels to the internal atomic displacement parameter has been emphasized by Van de Walle and Martin.\(^7\)

Deviations from the deformation potential approximation for short-wavelength acoustic phonons can be seen directly from the \( \mathbf{q} \)-dependence of \( \delta E \). For a given type of phonon, \( \delta E \) is linearly proportional to \( \mathbf{q} \) for small \( \mathbf{q} \). For larger \( \mathbf{q} \), we will see deviations from linearity. The long-wavelength deformation potentials can be found from the linear term obtained in a polynomial fit of the calculated \( \delta E/\delta R_0 \) vs \( \mathbf{q} \).

Another method for obtaining \( \Xi_\gamma \) from Eq. (39) is to strain a primitive cell so that previously degenerate valleys break their degeneracy. The difference in energy between the valleys is then proportional to \( \Xi_\gamma \). This method has been previously used by van de Walle and Martin\(^7\) to obtain \( \Xi_\Delta \) for Si and \( \Xi_\Delta^L \) for Ge. Since \( \Xi_\Delta^L \) can only be obtained from an absolute shift in band energies, the shift in potentials must be obtained using a supercell heterostructure with a strained region next to an unstrained one.

The calculation of the scattering rate is accomplished following Herring and Vogt\(^6\) using Eq. (39) to calculate the squared matrix element along symmetry directions of the phonon wave vector and interpolating these with spherical harmonics to obtain its angular dependence. The relaxation times (or scattering rates) are calculated, inserting our deformation potentials into Eqs. (49) and (50) of Ref. 6. Experimental values of the elastic constants for Si and Ge are used, linearly interpolated with respect to Ge composition \( x \) to obtain those of the alloy.

V. EXPRESSION FOR TOTAL MOBILITY

Finally, to calculate the total mobility due to all the scattering processes we apply a formula similar to that used in Ref. 1, derived from the Boltzmann transport equation in the relaxation time approximation:

\[
\mu_\gamma = \frac{4}{9 n^3 k_B T} \left( \frac{1}{m_r^\gamma} + \frac{2}{m_t^\gamma} \right) \int \rho(E)(E-E^\gamma)_+^{\gamma(E)},
\]

where \( \tau^\gamma \) is the sum of the different contributions to the scattering, namely, the alloy, intra- and intervalley and optical phonon scattering of a valley of type \( \gamma = \Delta \) or \( L \),

\[
\tau = \tau_{ac} + R_{\text{alloy}} + R_{\text{interval}},
\]

\( \tau_{ac} \) is the acoustic phonon relaxation time, and \( R_{\text{alloy}} \) and \( R_{\text{interval}} \) are the elastic alloy and phonon intervalley scattering rates, respectively. \( N_{\Delta}^L = 6 \) and \( N_{L}^L = 4 \) are the number of valleys in the \( \Delta \) and \( L \) bands, \( \rho^\gamma \) is the electronic density of states, and \( n^\gamma \) is the density of carriers in all valleys of type \( \gamma \).

\[
n^\gamma = 2N_{\Delta}^L m_r^\gamma m_t^\gamma \left( \frac{k_B T}{2\pi \hbar^2} \right)^{3/2} e^{E_F-E^\gamma/k_B T},
\]

where \( E_F \) is the Fermi energy.

Numerically, Eq. (46) does not have to be integrated up to infinity, thanks to the decaying exponential due to the Boltzmann distribution. 10 \( k_B T \) represents a good upper limit of integration. The total mobility is obtained by summing over the bands as follows:

\[
\mu = \sum \gamma r_\gamma \mu^\gamma,
\]

where
and $n = \sum n^\gamma$ is the total carrier concentration.

VI. DETAILS OF ELECTRONIC STRUCTURE CALCULATIONS

Density functional theory total energy calculations are performed with the ABINIT code.\textsuperscript{30,31} We use the local density approximation (LDA) for exchange and correlation. FHI pseudopotentials (available in the ABINIT website\textsuperscript{31}) are used for all calculations in this paper. The calculation of the various parameters requires different cell sizes, $k$-point densities and energy cutoffs, which are described below. We use an energy cutoff of 18 hartree for the expansion of wave functions in all our calculations. The calculation of the electronic band dispersion has been performed as in Ref. 10.

A. Inelastic intervalley and optical scattering calculation

The intervalley and optical phonon scattering matrix elements $H_{kk'}$ and the dynamical matrices are obtained in a diamond primitive unit cell, using the response function method,\textsuperscript{29} available in the ABINIT code.\textsuperscript{30,31} The modes and frequencies for the random alloy using random mass approximation are calculated in a 512-atom supercell with basis vectors,

$$A_1 = 4a_0(1,0,0),$$

$$A_2 = 4a_0(0,1,0),$$

$$A_3 = 4a_0(0,0,1).$$

The phonon density of states is validated against a 1000-atom supercell, while all other calculations are performed using a 512-atom supercell. In calculating the function $F_{\delta\alpha}(E)$, the delta function in Eq. (32) is replaced with a finite-width Gaussian: $\delta(E - \hbar \omega) \rightarrow \exp[(E - \hbar \omega)^2/2\sigma^2]/\sqrt{2\pi}\sigma^2$, where $\sigma = 3$ cm$^{-1}$, is chosen to be comparable to the typical separation between high-frequency mode frequencies $\omega_i$ in the finite supercell.

B. Frozen phonon calculation

In the frozen phonon calculations, we use the long supercells defined in Sec. IV C to obtain the energy splittings and
TABLE III. Calculated electron-phonon scattering matrix elements $H_{kk'}^{\alpha,\alpha'}$ (defined in Sec. IV B), with $\alpha$ as the Cartesian component, for the intervalley and optical scattering at the $\Delta$ and $L$ valleys in Si$_{1-x}$Ge$_x$, as functions of alloy composition $x$. The intravalley optical phonon matrix element is labeled $opL$. Scattering by optical phonons with the $\Delta$ valleys is forbidden by symmetry. All quantities are in $10^9$ eV/m.

VII. RESULTS

A. Scattering parameters

1. Elastic scattering parameters

The elastic alloy scattering matrices have been calculated from first principles and have been given in Ref. 10. In this section we show that atomic relaxation near the Si or Ge atom in the supercell is found to have an important effect on the scattering factors; in some cases the scattering intensity is twice as large as that calculated keeping all atoms in their ideal diamond lattice positions, as can be seen in Fig. 3 for a Ge atom in a pure Si supercell.

2. Intervalley phonon scattering parameters

Figure 4 shows the phonon dispersion for zincblende Si$_{0.5}$Ge$_{0.5}$ calculated in various approximations. We see that the phonon dispersion calculated with VCA interatomic forces is extremely close to that found from a full LDA calculation. This result suggested the use of random mass approximation to calculate the phonon frequencies and modes in a random alloy. We also test the use of random mass approximation against a full calculation of a 16-atom random alloy, shown in Fig. 5. While there are some minor differences, the approximation yields good peak positions and intensities.

Figure 6 shows the density of states of a disordered Si$_0.5$Ge$_{0.5}$ alloy calculated using random mass approximation.
TABLE IV. Calculated deformation potentials at the Δ and L valleys in Si_{1-x}Ge_x as functions of alloy composition x. All quantities are in eV.

in a 1000-atom supercell. The DOS of an alloy with an average mass \( m_{\text{avg}} = x m_{\text{Ge}} + (1-x) m_{\text{Si}} \) is also shown. The disordered DOS compares well to previous calculations and experiment. Notice that at very low frequencies the average mass density of states mimics that of the disordered supercell, justifying the argument presented in Sec. IV C for the use of an average mass to calculate the intravalley phonons.

We calculate the inelastic intervalley and optical phonon scattering rates from first principles for random alloys for Ge compositions of \( x=0, 0.25, 0.5, 0.75, \) and 1. The VCA electron-phonon matrix elements \( \mathbf{H}_{\alpha\beta}^\ast \) are shown in Table III, as functions of \( x \). To calculate the mobility, the intervalley scattering rates are interpolated in \( x \) for every value of energy \( E \). Figure 7 shows the spectral resolution of the electron-phonon interaction \( F(E) \) ([see Eq. (32)]) for a Ge composition of \( x=0.5 \), with and without using random mass approximation. The inverse mobility shown in Fig. 9 is calculated using random mass approximation, but we should note that, using the average mass approximation, the contribution of the optical and intervalley scattering is reduced by only 6% in the mobility, which amounts to a 1% reduction in the total mobility at Ge composition \( x=0.5 \).

3. Intravalley phonon scattering parameters

We calculate the deformation potentials \( \Xi_\alpha \) and \( \Xi_\beta \) from first principles with the method described above for the Δ and L valleys at Ge compositions of \( x=0, 0.25, 0.5, 0.75, \) and 1. Results are shown in Table IV, interpolated as functions of \( x \). Table V compares our calculated deformation potentials with calculations by Van de Walle and with experiment. Figure 8 shows the calculated \( C \cdot M_{\mathbf{k} \cdot \mathbf{q}} \) from Eqs. (42) and (44) for different values of \( \mathbf{q} \) in the directions specified in Table II for the L valley in pure Ge. The “d” line corresponds to a longitudinal phonon with \( \mathbf{q} \) in the [011] direction. The line labeled “u” represents \( 3C \cdot M_{\mathbf{k} \cdot \mathbf{q}} \) for a transverse phonon with \( \mathbf{q} \) along the [010] direction, for convenience. We can observe the deviations from the deformation potential approximation as \( q \) increases.

The intravalley phonon scattering rate is very important in determining the mobility in pure silicon or germanium, as can be inferred from Fig. 9. Equations (49) and (50) in Ref. 6 show the dependence of the scattering rate on the square of the deformation potentials \( \Xi_\alpha \) and \( \Xi_\beta \) as well as on their product. It is therefore crucial to calculate these as accurately as possible, since minor errors influence the mobility considerably.

B. Mobility

In Fig. 9 we present the contributions to the inverse mo-
agreement is excellent with Glicksman\textsuperscript{17} and Amith\textsuperscript{33} who
the peaks at
interband
leys are very close in energy, both the elastic and inelastic
mobility for most of the range of compositions, except at
pure Si or Ge, where acoustic scattering is of much greater
mobility of the different scattering processes calculated from the
Boltzmann transport equation in the relaxation time approxima-
tion (see Sec. V). It can be observed that the elastic alloy
scattering is the most important contribution hampering the
mobility for most of the range of compositions, except at
pure Si or Ge, where acoustic scattering is of much greater
significance. Acoustic phonon (intravalley) scattering domi-
nates over intervalley and optical phonon scattering, except
around the $\Delta-L$ valley crossover; here, where the two val-
leys are very close in energy, both the elastic and inelastic
interband $\Delta-L$ scattering become important, as shown by
the peaks at $x \approx 0.85$.

Figure 10 shows the calculated total mobility as a func-
tion of alloy composition, compared to experiment. The
agreement is excellent with Glicksman\textsuperscript{17} and Amith\textsuperscript{33} who
used single-crystalline samples, while the mobility is higher
than that of Busch and Vogt\textsuperscript{32} as was expected since they
used polycrystalline samples and did not subtract the ionized
impurity scattering contribution.

ing (dash in inset), and experimental data from Refs. 32 (triangles),
17 (squares), and 33 (stars).}
\end{figure}

\section{VIII. CONCLUSION}

We present the first full \textit{ab initio} calculation, the disor-
dered phonon $n$-type intervalley scattering parameters, and
and the acoustic deformation potentials for SiGe alloys as func-
tions of alloy composition, using supercell methods to nu-
merically represent the alloy scattering problem.

We find that, while disorder plays a crucial role in elastic
alloy scattering, it does not affect the overall strength of the
phonon scattering substantially, in spite of the loss of phonon
momentum conservation. This result points out that, in spite
of the fact that alloy disorder is essential in reproducing the
three optical peaks in the phonon density of states, as found
by de Gironcoli \textit{et al.},\textsuperscript{33} an average mass model for the pho-
non structure is sufficient for obtaining the correct contribu-
tions of optical and intervalley phonon scattering to the car-
rier mobility.

We test the validity of the deformation potential approxi-
mation by calculating them at different phonon wave vectors,
and find it to be good for scattering wave vectors dominant at
room temperature. Optical and intervalley parameters, as
well as the acoustic deformation potentials, are presented as
functions of alloy composition in Tables III and IV, respec-
tively.

We use our calculated scattering parameters in the Boltz-
mann transport equation to find the $n$-type mobility at room
temperature. The resulting mobilities are in excellent agree-
ment with experiment, in particular near the $\Delta-L$ band
crossing region. The \textit{ab initio} methods developed here are
broadly applicable to a wide range of semiconductor alloys.
