Title: Water sorption-induced crystallization, structural relaxations and strength analysis of relaxation times in amorphous lactose/whey protein systems

Article Type: Research Article

Keywords: Dynamic Dewpoint Isotherms; Crystallization; α-Relaxation; Relaxation Times; Strength; Water Activity

Abstract: Water sorption-induced crystallization, α-relaxations and relaxation times of freeze-dried lactose/whey protein isolate (WPI) systems were studied using dynamic dewpoint isotherms (DDI) method and dielectric analysis (DEA), respectively. The fractional water sorption behavior of lactose/WPI mixtures shown at aw ≤ 0.44 and the critical aw for water sorption-related crystallization (aw(cr)) of lactose were strongly affected by protein content based on DDI data. DEA results showed that the α-relaxation temperatures of amorphous lactose at various relaxation times were affected by the presence of water and WPI. The α-relaxation-derived strength parameter (S) of amorphous lactose decreased with aw up to 0.44 aw but the presence of WPI increased S. The linear relationship for aw(cr) and S for lactose/WPI mixtures was also established with R² > 0.98. Therefore, DDI offers another structural investigation of water sorption-related crystallization as governed by aw(cr), and S may be used to describe real time effects of structural relaxations in noncrystalline multicomponent solids.
Water sorption-induced crystallization, structural relaxations and strength analysis of relaxation times in amorphous lactose/whey protein systems

Abstract: Water sorption-induced crystallization, α-relaxations and relaxation times of freeze-dried lactose/whey protein isolate (WPI) systems were studied using dynamic dewpoint isotherms (DDI) method and dielectric analysis (DEA), respectively. The fractional water sorption behavior of lactose/WPI mixtures shown at \( a_w \leq 0.44 \) and the critical \( a_w \) for water sorption-related crystallization \( (a_w^{(cr)}) \) of lactose were strongly affected by protein content based on DDI data. DEA results showed that the α-relaxation temperatures of amorphous lactose at various relaxation times were affected by the presence of water and WPI. The α-relaxation-derived strength parameter \( (S) \) of amorphous lactose decreased with \( a_w \) up to 0.44 \( a_w \) but the presence of WPI increased \( S \). The linear relationship for \( a_w^{(cr)} \) and \( S \) for lactose/WPI mixtures was also established with \( R^2 > 0.98 \). Therefore, DDI offers another structural investigation of water sorption-related crystallization as governed by \( a_w^{(cr)} \), and \( S \) may be used to describe real time effects of structural relaxations in noncrystalline multicomponent solids.

1. **Introduction**

Water is of key importance to food systems affecting processing, microbial safety, sensory perception, and a storage stability and shelf life (Al-Muhtaseb, McMinn, & Magee, 2002; Lodi & Vodovotz, 2008). Water sorption may be affected by time-dependent phenomena, structural transformations, and phase transitions of food solids. Such transitions may affect rates of deteriorative changes and decrease the storage stability of dehydrated foods, e.g., powdered milk (Silalai & Roos, 2011), potato flakes (Turner et al., 2006), and dry pasta (Aguilera, Chiralt, & Fito, 2003; Gowen, Abu-Ghannam, Frias, & Oliverira, 2008). Water sorption isotherms are important to numerous applications, e.g., development of new products (Wang & Brennan, 1991), determination of product stability and shelf life (Jouppila & Roos, 1994), and process design and control (Peng, Chen, Wu, & Jiang, 2007). The dynamic dewpoint isotherm (DDI) method was developed to generate water sorption isotherms using single samples in a dynamically changing water vapor pressure (Yuan, Carter, & Schmidt, 2011). The DDI method developed along with dynamic vapor sorption provides a continuous measurement of water content ($c_w$) and water activity ($a_w$). DDI differs from standard saturated salt solution methods (SSM), which measure $c_w$ for equilibrated materials at known $a_w$ (Schmidt & Lee, 2012). Also, DDI makes it possible to generate complete dynamic isotherms with 50 to 200 data points quickly and accurately without long equilibration times which are typical of SSM methods (Yuan et
Therefore, DDI method offers another real-time investigation of water sorption-related material properties, i.e., crystallization and deliquescence (Yao et al., 2011), in food processing as well as for the control of storage stability and shelf life of resultant products.

Water sorption characteristics, as well as other interactions of food solids with water, are defined by composition of nonfat components, i.e., carbohydrates and proteins (Roos & Drusch, 2015). Characterization of glass formation of complex food solids systems has been of particular interest in recent years (Ibach & Kind, 2007; Babu & Nangia, 2011). Amorphous food materials exist in a supercooled and non-equilibrium state below their respective equilibrium melting temperature with no well-defined structure. The nonequilibrium state may exhibit an indefinite number of glass structures with varying levels of molecular packing and order. When temperature increases to above glass transition temperature ($T_g$), a rapid increase of molecular mobility occurs and the glass-forming material transforms to a viscous liquid, which dramatically affects various physicochemical properties of food solids (Slade, Levine, & Reid, 1991; Bhandari & Howes, 1999). Structural relaxations in amorphous food materials around or above the glass transition occur as a result of molecular mobility changes due to variations in external thermodynamic conditions e.g., pressure and temperature. Glass transition may also result internally in materials because of changes in plasticizer or
solvent contents, e.g., water, which can induce dramatic changes in solids properties and directly affect processing, storage, bioavailability, and delivery properties of food materials (Yu, Li, & Sun, 2001; Roos & Drusch, 2015). Relaxation times ($\tau$) correspond to the kinetically impeded and time-dependent molecular rearrangements that are responsible for solids structure and properties, e.g., flow characteristics, viscous flow and collapse, mechanical or dielectric properties, and crystallization (Sperling, 2005). Such properties may be used to control the quality and stability of food materials during processing and storage (Champion, Le Meste, & Simatos, 2000).

The $\alpha$-relaxation and relaxation times of glass forming food materials around calorimetric $T_g$ could be studied and determined by dielectric analysis (DEA) (Moates, Noel, Parker, & Ring, 2001; Clerjon, Daudin, & Damez, 2003). The $\alpha$-relaxation temperature ($T_\alpha$) may also be taken from the dielectric loss ($\epsilon''$) peak temperature at various frequencies to obtain corresponding relaxation times (Silalai & Roos, 2011). The Williams-Landel-Ferry (WLF) model is often used to model relaxation times of the non-Arrhenius temperature dependence of relaxation processes occurring above $T_g$, and the $\tau$ is shown against $T-T_g$ (Slade, Levine, & Reid, 1991). The WLF-relationship applies over the temperature range covering the rubbery or supercooled liquid state and it was also used to describe time and temperature dependent behavior of food solids systems. The “strength” concept and strength parameter ($S$) developed by Roos and
others (2015) combined the characterization of material state and relaxation times to describe the critical temperature difference at which a sharp change in properties of the material occurs. On the other hand, the $S$ parameter based on WLF modeling was used to describe amorphous food solids and their properties for typical processing and storage conditions where a component or miscible components within food structure may experience the glass transition (Fan & Roos, 2016a). Besides the strength of food solids, the Deborah number was applied to provide a useful translation of measured relaxation times to real timescales. Therefore, the strength concept gives a quantitative measure to estimate compositional effects on relaxation times to describe properties of food solids above measured $T_g$.

Lactose ($\beta$-D-galactopyranosyl (1–4)-D-glucopyranose) is one of the most common and important ingredients in many formulated foods and pharmaceutical materials, and it exhibits strong water-dependent properties, i.e., glass transition and crystallization from its amorphous states during storage (Nickerson, 1979; Gänzle, Haase, & Jelen, 2008). Understanding glass transition-related structural relaxations and their coupling with water sorption properties is essential for modeling the physical state of dairy-based food systems at various conditions and the design of complex formulations. The importance of glass transition to amorphous solids characteristics has been well recognized but few studies have contributed to understanding effects of glass former or
polymer, i.e., protein, on the water sorption characteristics and structural relaxations in food formulations. Therefore, the major objective of the present study was to investigate the influence of food polymeric components (whey protein isolates, WPI) on the water sorption properties of freeze-dried amorphous lactose/WPI mixtures using the DDI measurement data at 25 °C. The strength analysis was carried out to determine the $S$ parameter for lactose/WPI systems by analyzing their relaxation times measured by DEA after storage at $a_w \leq 0.44$ and 25 °C. These data are useful for the understanding of the effects of proteins on water sorption properties of amorphous lactose and collective structural relaxation behavior when present with amorphous lactose around the glass transition in well-mixed food and pharmaceutical materials.

2. Materials and Methods

2.1. Sample preparation

$\alpha$-Lactose monohydrate (>99 % lactose) (Sigma-Aldrich, St. Louis, Mo., U.S.) and whey protein isolate (WPI; Isolac®, Carbery Food Ingredients, Co., Ballineen, Ireland; minor components including carbohydrates or lipids < 3%) were used. Aqueous lactose and WPI with 20 % (mass) solids at room temperature were used to obtain ratios of 7:3, 1:1 and 3:7 of lactose/WPI by mass. Mixed solutions (5 mL in total) were prepared in pre-weighted glass vials (10 mL; Schott Müllheim, Germany). All solutions in the vials
(semi-closed with septum) were frozen at -20 °C for 20 h and then subsequently tempered at -80 °C for 3 h prior to freeze-drying using a laboratory freeze-dryer (Lyovac GT2 Freeze-Dryer, Amsco Finn-Aqua GmbH, Steris®, Hürth, Germany).

After freeze-drying at pressure < 0.1 mbar, triplicate samples of each material were stored in evacuated desiccators over $P_2O_5$ at 25 °C (Sigma-Aldrich, St. Louis, Mo., U.S.) prior to subsequent analysis.

2.2. Water sorption experiment

The water sorption of freeze-dried samples was studied using an AquaSorp isotherm generator (AIG; Decagon Devices, Inc. Pulman WA, USA). The airflow continuously passes over the sample in AIG until certain interval time or when there was a mass or $a_w$ change of sample, then the flow stopped and the snapshot of the sorption process was taken by directly measuring mass and $a_w$ based on a high precision magnetic force balance and chilled-mirror dewpoint sensor (Decagon Devices, Inc. Pulman WA, USA). Based on above principle the dynamic water sorption of DDI can be comparable to real-time sorption process for a material with fast vapor diffusion or by reducing the sample size. In the present study, approximately 600 mg of each sample (dried powder), which could cover the bottom of stainless steel sample cup, was used in measurements. Measurement parameters were 0.05 to 0.90 $a_w$ at a temperature of 25 °C,
airflow of 300 ml/min (Schmidt & Lee, 2012). At certain interval time, the airflow stopped automatically then the weight change and the $a_w$ of the sample were recorded. After initial $c_w$ was determined, the mass was converted to the $c_w$ of the sample at the corresponding $a_w$ and a plot of the dynamic sorption isotherm using the SorpTrac software, version 1.03.3 (Decagon Devices, Pullman, WA, USA) was generated. Since each DDI run is unique, the sorption section of the working isotherm was obtained in duplicate, each on a different sample.

The critical $a_w$ value for water sorption-induced crystallization ($a_w^{(cr)}$) of lactose and lactose/WPI mixtures were analyzed and determined by calculating the changes of $c_w$ in DDI of each sample using derivative analysis (Yuan et al., 2011). The procedures used to obtain the first and the second derivative was as follows. Attempts to leave out noise and find the peak location, the $a_w$ and $c_w$ data derived from DDI were smoothed using LOESS (local polynomial regression fitting) smoothing (second-degree polynomial) with a span of 11 points using the R programme, version 3.2.3 (The R Foundation ©, Murray Hill, NJ, USA). The smoothed data set was fit using a smoothing cubic spline after which the first derivative of the fit was taken. The peak $a_w$ of the 1st derivative function ($a_{wp}^{(cr)}$) based on smoothed DDI data was taken as acceleration point for
lactose crystallization. The smoothing and fitting procedures were repeated for the 1st derivative after which the 2nd derivative was obtained from the 1st derivative. Water sorption data showed that a substantial peak on the 2nd derivative developed with onset around the calorimetric $T_g$ corresponding $a_w$, $a_{w0}^{(c)}$ (Fig. 1A). The water plasticization to above the glass transition induced translational mobility of lactose. Such mobility with further water plasticization could increase free volume to provide water sorption sites and hydrogen bonding structuring of the lactose-water system to accommodate water with less direct lactose-lactose interactions. The programmed codes for achieving first and second derivative analysis in R programme were shown on Supplementary Information.

2.3. Dielectric analysis (DEA)

DEA was used to measure dielectric properties from the dielectric constant or permittivity ($\epsilon'$), dielectric loss ($\epsilon''$), and their ratio $\tan \delta = (\epsilon''/\epsilon')$ as a function of temperature. The $\epsilon'$ describes an alignment of dipoles and the $\epsilon''$ describes an energy that is required to align dipoles (Talja & Roos, 2001). In the present study, the freeze-dried lactose and lactose/WPI at 7:3, 1:1 and 3:7 mass ratios were humidified for 120 h over saturated solutions of $CH_3COOK$, $MgCl_2$, and $K_2CO_3$ (Sigma Chemical Co., St. Louis, Mo., USA) to obtain respective water activities of 0.23, 0.33 and 0.44 $a_w$ at
equilibrium in vacuum desiccators in incubators at storage temperature of 25 °C.

Dielectric properties of both dry and humidified samples were analyzed using dielectric analyzer (DS6000, Triton Technology Ltd., UK), with titanium sample holders as the electrodes. The LCR meter (inductance, capacitance, and resistance; LCR-819) and DEA instrument were calibrated and zeroed with the open-short circuit of the electrodes before starting experiments. Samples were ground and approximately 600 mg samples were placed between parallel plate titanium capacitors (diameter = 33 mm) with the thickness less than 2 mm. Triplicate samples of each material were analyzed using dynamic measurements and recorded using Triton Laboratory software (version 1.0.330). Samples were analyzed in triplicate using dynamic measurements and scanned from ~ 60 °C below to over the $T_g$ region with cooling rate of 5 °C/min and heating rate of 2 °C/min at frequencies of 0.5, 1.0, 5.0, 10.0 and 20.0 kHz. The measuring head was connected to a liquid nitrogen tank (1L; Cryogun, Brymill cryogenic systems, Labquip (Ireland) Ltd., Dublin, Ireland). As noted above, $T_\alpha$ determined from the temperature of $\varepsilon''$ at the peak were used to determine the relaxation times.

2.4. Strength analysis
The relaxation times and $T_\alpha$ corresponding to $\varepsilon''$ peak above $T_g$ were modeled using the WLF equation (Eq. 1). The relaxation times were defined by frequency set in DEA measurements ($\tau = 1/2\pi f$). The WLF model constants $C_1$ and $C_2$ were derived from a plot of $1/\log(\tau/\tau_g)$ against $1/(T-T_g)$ using experimental $\tau$ with the assumption of $\tau_g = 100$ s at the calorimetric onset temperature of the $T_g$ (Angell 2002). A decrease in the number of logarithmic decades for flow, e.g., that being critical for stickiness, could be used as the critical parameter, $d_s$, of Eq. (2) and the corresponding $T-T_g$ was defined as the strength of the solids, $S$. As the $S$ values are given as temperature corresponding to a critical $\tau$ for a key amorphous component within a material, it also provides a measure of resistance to structural changes, i.e., the higher value of $S$ refers to a stiffer system at a corresponding $T-T_g$. 

\[
\log\left(\frac{\tau}{\tau_g}\right) = \frac{C_1(T - T_g)}{C_2 + (T - T_g)} \quad \text{(1)}
\]

\[
S = \frac{d_s C_2}{C_1 d_s} \quad \text{(2)}
\]

Where, $T$, $T_g$, $\tau$, $\tau_g$, $C_1$ and $C_2$ and $d_s$ shown in Eq (1) and (2) refer to the experimental temperature, onset glass transition temperature, experimental structural relaxation time and structural relaxation time at the glass transition ($\tau_g = 100$ s), material-specific WLF constants and the decrease in the number of logarithmic decades for $\tau$ ($d_s = 4$ was used.
for various biological materials as reported by Roos et al. (2015) and Fan and Roos (2016b), respectively.

2.6. Statistical analysis

The second derivative analysis of DDIs sorption data was carried out in R Programme and the strength analysis of dielectric α-relaxation associated relaxation times were calculated and fitted by using Microsoft Office Excel 2011 (Microsoft, Inc., USA). All measurements were repeated three times, as well as the average values with the standard deviation of triplicate measurements were calculated.

3. Results and Discussion

3.1. Dynamic Water Sorption

Table 1 and Fig. 2

The DDI for pure lactose ($a_w \leq 0.50$), WPI and lactose/WPI mixtures with the mass ratios of 7:3 ($a_w \leq 0.70$), 1:1 ($a_w \leq 0.80$) and 3:7 followed the typical sigmoid shape of water sorption isotherms (type II) in Fig. 1B, respectively. The fractional water sorption of components, exhibited by amorphous sugar/protein mixtures, has been
reported by previous studies (Roos & Potes, 2015). Similarly, the fractional water 
sorption properties were proved in DDIs as the sorbed water in amorphous lactose/WPI 
mixtures could be calculated as the sum of fractional quantities at $a_w \leq 0.44$ (Fig. 1B). 
However, if water sorption rates of components vary DDI data may reflect such 
differences. Fig. 2 gives the DDI water sorption and literature SSM data for 
freeze-dried lactose and lactose/WPI mixtures at 7:3, 1:1 and 3:7 mass ratios at 25 °C 
(Fan & Roos, 2015). The water contents in DDIs of lactose were lower than those of 
corresponding SSM isotherms (Fig. 2A). Such differences in the DDI sorption data 
reflected the non-equilibrium state of amorphous solids and the relatively short 
equilibration time in comparison to SSM giving a systematic error for the water content 
as full dehydration may not take place at low $a_w$. The SSM-isotherms comparable $c_w$ 
data are shown on the DDIs of lactose/WPI mixtures at various protein contents (Fig. 
2B-D). The DDI sorption data of pure amorphous WPI, however, showed 
shape-comparable sorption isotherms to corresponding SSM isotherms (Fig. 2E). Such 
similarity in water sorption by the two methods indicated that the amorphous WPI 
showed a slow equilibration reducing time to water vapor diffusion and water 
penetration during DDI sorption. The DDI sorption data for amorphous lactose leveled 
off at high water activities ($\geq 0.50 a_w$) as a result of lactose crystallization (Fig. 2A). In 
lactose/WPI systems lactose molecules form a continuous phase around WPI 
molecules, but WPI components may hinder diffusion of the noncrystalline lactose. In 
comparison to pure lactose, therefore, the presence of WPI in lactose/WPI mixtures
delayed crystallization and extended the sigmoid sorption behaviors to a higher $a_w$ range (Fig. 2B-C). This phenomenon agreed with previous studies, which indicated that the crystallization of lactose could be delayed by the presence of polymeric components (Silalai & Roos, 2011). As noted above, the presence of other components, e.g., protein, with amorphous sugars, affected water sorption as well as the crystallization as a result of water plasticization.

Fig. 3

The $a_w^{(cr)}$ values of amorphous lactose and lactose/WPI mixtures at each ratio are shown in Table 1, respectively. Fig. 2F showed a linear relationship with high correlation coefficient ($R^2 > 0.98$) for $a_w^{(cr)}$ values against lactose content of amorphous lactose/WPI systems at 25 °C, which indicated that the $a_w^{(cr)}$ was that of the lactose component rather than for the entire system although protein affected structural relaxation times (Roos & Potes, 2015). In the present study, the $a_w^{(cr)}$ was considered as a critical $a_w$ point for glass-forming lactose plasticized by water to flow and accommodate increasing free volume and water uptake during DDI sorption process. The $a_w^{(cr)}$ was a turning point where the rate of water uptake became less than the rate of lactose crystallization. Corresponding to previous X-ray study (Jouppila et al., 1997), therefore, we assumed that the $a_w^{(cr)}$ and $a_w^{(cr)}$ were the onset and half-crystallinity
point of lactose crystallization, respectively. In the present study, the $a_{w_0}^{(cr)}$ of pure amorphous lactose occurred at 0.381 $a_w$ at 25 °C (Table 1). This result agreed with previous calorimetric studies that the glass transition of freeze-dried lactose after humidification at 0.44 $a_w$ at room temperature was around 15 °C as well as the critical $a_w$ of 0.37 of amorphous lactose (Fan & Roos, 2016a). Both onset and peak $a_w^{(cr)}$ values of lactose/WPI mixtures increased concomitantly with increasing protein content (Table 1). Fig. 3 gives a schematic diagram for the dynamic water sorption process of amorphous lactose and lactose/WPI mixtures. From I to II (Fig. 3A), the water sorbed by amorphous lactose could plasticize the structure of glass formers resulting in breaking the hydrogen bonds between lactose molecules and the relaxation times of amorphous lactose decreased (Slade et al., 1991). As $a_w$ increased to above $a_{w_0}^{(cr)}$, the mobilization of glass formers was strongly enhanced by water plasticization (Fig. 3A II-III). When the $a_w$ exceeded $a_{wp}^{(cr)}$, the lactose crystallinity rapidly increased until most of lactose crystallized during the DDI sorption process (Fig. 3A III-IV). However, the presence of WPI hindered water plasticization effects as the $a_{w_0}^{(cr)}$ increased in lactose/WPI mixtures (Fig. 3B II-III). Moreover, the $a_{wp}^{(cr)}$ of lactose/WPI mixtures increased concomitantly with the WPI content and delayed the lactose crystallization in mixtures (Fig. 3B III-IV). Therefore, the $a_w^{(cr)}$ values of the DDI data indicate the glass transition resulting in mobilization and crystallization of amorphous lactose in food and pharmaceutical materials.
3.2. Dielectric properties and $T_\alpha$

Table 2 and Fig. 4

Fig. 4 shows the dielectric loss ($\varepsilon''$ peaks at a frequency of 1.0 kHz) for lactose and lactose/WPI mixtures with mass ratios of 7:3, 1:1 and 3:7 after storage below 0.44 $a_w$ at 25 °C. Dielectric properties of the materials were affected by molecular interactions and water plasticization. The magnitude of the $\varepsilon''$ peak correlated directly to $a_w$ of amorphous lactose at low water activities ($0.23 \leq a_w \leq 0.44$) as water content increased and plasticization enhanced the mobility of lactose molecules. This agreed with Silalai and Roos (2011) who reported that $\varepsilon''$ peaks found for skim milk powder increased in magnitude with increasing $a_w$ (Fig. 4A). The $\varepsilon''$ describes an energy loss that is used by polar groups in materials under the alternating electric field. The lower levels of WPI containing lactose/WPI mixtures ($\leq 30 \%$) showed higher magnitudes of $\varepsilon''$ peaks than pure lactose after humidification at the same $a_w$ and 25 °C (Fig. 4B-D). Therefore, the $\varepsilon''$ data followed the amorphous lactose content of the mixtures as WPI and lactose exist in separate phases. Table 2 gives the $T_\alpha$ value of each material in dielectric analysis at 1.0 kHz, which occurred above the corresponding calorimetric onset $T_g$ measured by differential scanning calorimeter (DSC) in agreement with Silalai and Roos (2011). The presence of water, in the present study, decreased the $T_\alpha$ values of amorphous lactose and lactose/WPI mixtures as the peak temperature of $\varepsilon''$ concomitantly
decreased with increasing $a_n$ (Table 2). The $T_α$ values of amorphous lactose could be significantly increased by WPI in lactose/WPI mixtures (Table 2). Lactose can be assumed to exist separated from protein. The frequency-dependent $T_α$ indicated an apparent relaxation time of lactose in WPI mixtures. Water plasticization enhanced the molecular mobility of lactose molecules which consequently decreased the peak temperature of $ε''$. However, the WPI contained in mixtures hindered the molecular mobility of lactose and increased the apparent relaxation times and $T_α$. In our previous studies, similarly, the presence of other components, i.e., water and protein, affected the structural relaxations, relaxation times and $T_α$ of glass-forming sugars in freeze-dried sugars/protein systems based on dynamic-mechanical analysis (DMA) (Fan & Roos, 2016a,b).

3.3. Relaxation times and S parameter

Both DEA and DMA measurements allowed determination of structural relaxation times from the $α$-relaxation data at various frequencies. The structural relaxation times can be related to stickiness characteristics of food powders as well as other mechanical
properties of food solids, such as the collapse of structure or viscosity and diffusion (Clerjon et al., 2003). Fig. 5 shows structural relaxation times from our experiments and literature (Fan & Roos, 2016a). The WLF-relationship of Williams et al. (1955) was developed on the basis that most inorganic and organic glass formers showed similar decreases in $\tau$ and viscosity over the temperature range of $T_g$ to $T_g+100$K. The use of WLF-relationships often assumes that the structural relaxation time obtained using dielectric measurements reach 100 s at the calorimetric onset $T_g$ (Angell, 2002; Roos et al., 2015). In the present study, the WLF-relationship with “universal” constants ($C_1 = -17.44$ and $C_2 = 51.6$) did not fit the experimental data but material-specific constants gave a good fitting performance for lactose and lactose/WPI mixtures at $a_w$ below 0.44 and 25 °C (Fig. 5). Table 2 gives material-specific WLF constants for amorphous lactose and lactose/WPI mixtures obtained from structural relaxation times of the DEA and published DMA measurements. The material-specific $C_1$ for amorphous lactose increased concomitantly with $a_w$ increasing, whereas both $C_1$ and $C_2$ decreased by the presence of WPI content at $a_w$ below 0.44 (Table 2). It is important to note that fitting of the WLF model to experimental relaxation times may result in positive or negative values or negative values for the constants $C_1$ and $C_2$ (Roos & Drusch, 2015). In the present study, the $C_1$ and $C_2$ with negative values determined the downward concavity for WLF relationship, which showed the profiles for the decreases of relaxation times of amorphous lactose at temperatures above calorimetric $T_g$. Therefore, the material-specific WLF constants could be used to
describe material properties and structural relaxation processes of amorphous lactose at various water activities. The presence of other components, e.g., water and protein, affected the structural overall relaxation processes as well as apparent relaxation times of lactose/WPI mixtures.

The decrease of relaxation times to $10^{-2}$ corresponded to a decrease in viscosity from $10^{12}$ Pa s to $10^{5}$ Pa s reaching critical viscosities for collapse and stickiness of amorphous food solids (Bellows & King, 1973; Downton, Flores-Luna, & King, 1982).

Roos et al. (2015) recommended a WLF model-based strength analysis for amorphous sugars/protein systems. The $S$ parameter for glass-forming components calculated by using material-specific WLF constants defined an allowable increase in temperature above the onset of the calorimetric $T_g$ until $\tau = 0.01$ s. As the lactose and protein diffusion was uncoupled the $S$ parameter followed relaxation times of amorphous lactose. Table 2 gives the $S$ values of amorphous lactose and lactose/WPI mixture at low $a_w$ based on the strength analysis using experimental structural relaxation times derived from DEA and published DMA data. In the present study, the $S$ values of freeze-dried lactose with different water activities agreed with our earlier data (Fan & Roos, 2016a). The presence of water decreased the structural strength of amorphous lactose at $a_w$ below 0.44, whereas the $S$ values of lactose/WPI mixtures were significantly higher than was found for pure lactose (Table 2). As the $S$ parameter
provides a measure of structural transformation, a low $S$ value referred to a more rapid structural change. Such rapid changes occurred in the presence of water as the structural relaxations of amorphous lactose were enhanced by water plasticization. However, the relatively higher $S$ exhibited by lactose/WPI mixtures indicated that the mixes were strengthened against structural deformation as protein offered a structural supporting effect. Therefore, the $S$ parameters based on dielectric/mechanical relaxations can be used to describe compositional effects of amorphous food solids systems. Such data can be used to control shrinkage in dehydration and possibly rates of physicochemical changes in food storage.

3.4. Sorption-induced crystallization, relaxation times and $S$ parameter

The relationships between $a_w$ and $T-T_g$ of amorphous lactose and lactose/WPI mixtures against their corresponding relaxation times are shown in Fig. 6A. The water-induced structural relaxations of food solids systems, observed in isothermal water sorption, are likely to correlate with crystallization above glass transition. The relaxation times of lactose dramatically decreased with increasing $T-T_g$ as the $T_g$ was depressed by water
The crystallization of lactose was initialized above $a_{w_{\text{cr}}}$ and rapidly occurred along decreasing structural relaxation times during water sorption process. The water sorption-induced lactose crystallization could stop at 0.7 $a_w$ based on the DDI sorption data, where the $\tau$ decreased approximately 4 logarithmic decades (Fig. 6A). As we expected, the $a_{w_{\text{cr}}}$ for water-induced crystallization was delayed to occur at higher $a_w$ in the presence of WPI (Fig. 6A). The decrease of structural relaxation times, $a_{wp_{\text{cr}}}$ and crystallization of amorphous lactose can be controlled by WPI during exposures to high humidities (Fig. 6A). Fig. 6B shows a plot of onset and peak $a_{w_{\text{cr}}}$ against $S$ for anhydrous lactose and lactose/WPI mixtures. There was a linear relationship between $a_{w_{\text{cr}}}$ and $S$ with high correlation ($R^2 > 0.97$). The pure lactose had a lower $a_{w_{\text{cr}}}$ and $S$ value than WPI containing systems (Fig. 6B). This result indicated that the structural strength could be related to water-induced crystallization of amorphous sugars during isothermal water sorption. Therefore, we believe that the DDI provided parameters describe the structural changes and crystallization behavior of amorphous sugars during water plasticization. The $S$ parameter could be used to estimate time-dependent water sorption-induced solid properties of amorphous food mixtures during storage at various water activities, i.e., structural transformations and deformation. Moreover, proteins as commonly used components could be used in food and pharmaceutical systems to control water sorption properties as well as structural relaxation rates and crystallization.
4. Conclusion

We have shown that the freeze-dried lactose and lactose/WPI mixtures have fractional water sorption properties. Water sorption-induced relaxations and crystallization were delayed in the presence of WPI in amorphous lactose/WPI mixtures. The $T_\alpha$ values of amorphous lactose in lactose/WPI mixtures at $a_w \leq 0.44$ were affected by the mixture composition, i.e., water, and WPI. The WLF analysis based $S$ parameter with relaxation times data from DEA and DMA was dependent on mixture composition. It was used to interpret water sorption-induced crystallization of amorphous lactose in mixtures with WPI. The combination of dielectric and mechanical properties offers a new approach in understanding glass transition-related structural relaxations occurring in food processing and storage. Such information also advances innovations in food formulation through mapping of structural relaxation times of food components and their mixes.
