Low-cost, real-time gas detection for use in photocatalytic air-purification tests

This research demonstrates the use of a gas detector as a feasible alternative to the standardized analytical methods typically found in photocatalytic air purification ISO standard tests and academic literature. A methyl mercaptan detector is calibrated and validated (for linearity) using a standard gas generator. The detector can be directly connected to the photoreactor exit allowing real-time span gas measurement with data-logging at one minute intervals. The detector successfully differentiated samples with different photocatalytic performance. The use of such detectors offers an easy-to-use, low-cost alternative to gas measurement with applications in academic research, proof-of-concept photocatalytic tests and also as an educational tool.

1. Introduction

Photocatalysts are materials, which can accelerate chemical reactions by absorbing light quanta of suitable wavelengths depending on the band structure. Photocatalysts find a wide range of industrial applications ranging from self-cleaning materials to water purification. Various ISO (International Standard Organisation, the International Organization for Standardization) methods have been implemented to analyse the effectiveness of various types of photocatalysts, which can be employed by industries to test the products and thereby to ensure the quality of the product.

To date, there are five ISO photocatalytic air-purification test standards for the following test gases: Nitric Oxide (NO), Acetaldehyde (CH₃CHO), Toluene (C₆H₅O), Formaldehyde (CH₂O) and Methyl Mercaptan (CH₃SH). In 2012, Mills et al. reviewed the first three standards available at the time. As the authors point out, one of the disadvantages of the standards is that each individual sub-test requires expensive and different analytical equipment (listed here in Table 1). Other analytical methods such as ion chromatography (NO₃⁻) and an infrared analyser (CO₂) are recommended in the first two standards to measure photocatalytic by-products. Interestingly, the final three standards only describe measurement of the pollutant test gas. It was also pointed out that technical support and training is often needed for operation and maintenance of these analytical methods. Although the gas chromatographic methods are powerful and can quantitatively identify and measure photocatalytic by-products, the expense in cost and experimental man-hours can cause researchers to struggle to build the apparatus and also lose focus and time on the original goal of the standards (to test photocatalytic performance). Concerns such as these were described as ‘possibly unavoidable’. In this study we address the issue by employing a low-cost, commercially available “off-the-shelf” gas monitor as an alternative gas analyser for measurement of the fifth ISO standard test gas (methyl mercaptan) in photocatalytic air purification tests.

Methods are powerful and can quantitatively identify and measure photocatalytic by-products, the expense in cost and experimental man-hours can cause researchers to struggle to build the apparatus and also lose focus and time on the original goal of the standards (to test photocatalytic performance). Concerns such as these were described as ‘possibly unavoidable’. In this study we address the issue by employing a low-cost, commercially available “off-the-shelf” gas monitor as an alternative gas analyser for measurement of the fifth ISO standard test gas (methyl mercaptan) in photocatalytic air purification tests.

Although gas detectors used in photocatalytic experimental setups have been reported in the literature (a good example of a fixed methyl mercaptan detector is from Li et al.), such instances are rare, and not the primary purpose of the studies. Emerging analytical methods have also recently been proposed as alternatives to the ubiquitous GC methods described above in photocatalytic air-purification. Ireland et al. employed field asymmetric ion mobility spectrometry (FAIMS) to analyse the
photo-oxidation of indoor volatile organic compound (VOC) air pollutants. Yao et al.\textsuperscript{14} used proton-transfer-reaction mass spectrometry (PTR-MS) to characterise the photocatalytic degradation of odorous compounds associated with livestock. Both of these new analytical methods rival the standardized GC methods in terms of specification but do not address the principal concern of Mills et al.\textsuperscript{11} regarding cost and ease of use. In another interesting educational study, Stefanov et al.\textsuperscript{15} employed commercially available semiconductor gas sensors in a 3-D printed photocatalysis reactor. However, using such sensors require supporting electronics for digital readout and is not a “ready-to-use” gas detection system. The low-cost detector used in this study (Honeywell ToxiRae Pro) is portable, has on-line data logging capability and is inherently user-friendly as its primary purpose is in chemical site safety. Following analytical validation tests to determine linearity, the photocatalytic removal of methyl mercaptan is demonstrated employing glass beads coated with Evonik P25 titanium dioxide (TiO\textsubscript{2}). The advantages and disadvantages of employing such detectors are discussed as well as suitable applications and future research.

2. Materials and Methods

2.0 Materials

The calibration methyl mercaptan gas is generated using a standard gas generator (Kin-Tek 491MB). The generator employs NIST traceable permeation tubes as the span gas source. Both the generator and permeation tubes were supplied by Ecoscientific Limited. The variable area flow controller and all tubing were supplied by Fischer Scientific. All valves were supplied by Swagelok. The gas chambers, dreschel bottle and photoreactor tubes (90 mm length, 8 mm outer diameter, 5 mm inner diameter) were made by an in-house glass-blower. Evonik P25 TiO\textsubscript{2} powder, glass beads (710µm – 1180 µm) and glass wool were supplied by Sigma-Aldrich. The ToxiRae Pro (Honeywell, Rae Systems) gas monitor with CH\textsubscript{3}SH electrochemical senor (Range: 0-10 ppm, Resolution: 0.1 ppm) was supplied by Envirosafe Ireland. The humidity/temperature logger (Onset HOBO MX1101) was supplied by Tempcon.

2.1 Gas Detector Calibration and Validation

A methyl mercaptan gas detector (ToxiRae Pro) was employed as a test detector. Prior to each use the detector is calibrated by a connection via an adapter supplied with the detector to a gas standards generator as shown in Figure 1. The detector head is purged with calibration gas for 30 minutes prior to internal instrument detector calibration (1 min). The linearity validation test was performed by supplying the calibration span gas over a range indicated by the ISO standard\textsuperscript{10} (0-5 ppm) by changing the flow rate using a mass flow controller housed within the gas standard generator. The measured detector concentration was recorded at one minute intervals.

2.2 Preparation of photocatalytic tubes

Photocatalytic test materials were prepared by coating glass beads with Evonik P25 TiO\textsubscript{2} powder (Sigma Aldrich) using methods similar to those reported by Basha et al.\textsuperscript{16} 6g of glass beads, 0.6g of P25 powder and 240 cm\textsuperscript{3} of deionised water were placed in sealed 250 cm\textsuperscript{3} Schott glass bottle and sonicated in a bath for 1 hour at room temperature. The top of the bottle is removed and the bottle is placed in an oven at 110 degrees overnight. The dried, coated beads are removed, and the excess TiO\textsubscript{2} powder is removed by repeated washing with deionised water and sieving through a Test Sieve (Fisherbrand 200mm Diameter x 500 µm). The coated and uncoated beads are...

imaged by Scanning Electron Microscopy (SEM) (JEOL model FEI FP 2031/11 Inspect F field emission scanning electron microscope). Fixed quantities (2, 1.5, 1.0 and 0.5g) of the powder coated beads from the same batch are packed into glass photoreactor tubes between glass wool (Sigma Aldrich) and retaining springs (Markes International) for the photocatalytic air purification tests.

2.3 Experimental test setup

The photocatalytic air-purification test setup shown schematically in Figure 2, has features from different reported setups including the ISO standards$^{6-10}$, Idris et al.$^{17}$, Yu et al.$^{18}$ and Destaillats et al.$^{19}$ Compressed air is supplied to both the gas standards generator and the drenchel bottle. The span gas is humidified in a gas-mixing chamber and flows directly (flow path #1) to the humidity detector in the gas detection chamber, followed by the gas detector. The flow rate of the span gas and diluent humidified air are adjusted in the gas standards generator and variable area flow controller respectively, such that stable readings of 5.0 ± 0.3 ppm CH$_3$SH and 50 ± 5 % relative humidity are observed by the detectors. The plug valve and 3-way valve are then opened allowing the test gas to flow through the photoreactor tube to both detectors (flow path #2). Adsorption is observed by reduction in the CH$_3$SH reading on the detector. Once the reading returns to 5 ppm, the UV lamp is turned on to test the photocatalytic performance of the powder coated sample over a 3-hour period after which the lamp is turned off to ensure a return of the test gas to within 10 % of the test concentration.

3. Results and Discussion

3.1 Gas Detector Validation

The span gas target concentration was reduced from 5 to 0.9 ppm at one minute intervals by modifying the flow rate across the permeation tube$^2$ from 0.29 to 1.72 L/min with 80 data points. Figure 3 shows that the CH$_3$SH detector gives a highly linear response with an $R^2$ value of 0.999 and y-intercept of 0.11881. Both of these values can be considered as a good linearity fit as part of a general analytical method validation$^{20}$, and thus fit for purpose as a detector in the photocatalytic air-purification test setup.

3.2 Photocatalytic Air-Purification tests

Four samples with different quantities (2, 1.5, 1.0 and 0.5g) of TiO$_2$ coated glass beads from the same batch were tested in the photocatalytic test setup to demonstrate the applicability of the gas detector i.e. that the “method can differentiate (the) samples with different photocatalytic performance”$^{6-8}$. The coating method produced a thin film of TiO$_2$ as shown by equal magnification SEM in Figure 4. As opposed to TiO$_2$ in powder form, the coated beads showed minimal adsorption satisfying the ISO adsorption requirement: that the gas concentration at the outlet of the reactor returns to supply gas concentration within 30 minutes. To the naked eye the coated beads in the glass photoreactor tubes were semi-transparent allowing adequate UV illumination of the photocatalyst surface. Quantities of coated beads were tested allowing removal of CH$_3$SH within the range of that reported in the ISO standard$^{10}$ (0-5 ppm).

As shown in Figure 5 and Table 2, the gas detector was able to quantify the removal of the test CH$_3$SH pollutant gas of different performing photocatalytic coatings in a satisfactory manner, the primary goal of the ISO standard. Greater accuracy is obtained due to the data-logging capability of the detector in which 60 data points in the last hour of the test can be averaged to obtain $\phi_M$ (averaged concentration at reactor exit). This is in comparison to the ISO standards which recommend $\phi_M$ should be the average of at least three or more measurements. Without an automatic sampling system connecting the...

The table presents the removal percentage of methyl mercaptan for various samples of TiO2. The samples are tested under different conditions, and the removal percentage is calculated based on the initial and final concentrations of methyl mercaptan.

At a first glance at the schematic diagram of the overall test equipment in the ISO standards, the “pollutant-measurement equipment” appears straightforward (Figure 6 (a)), with a basic monitor, as used in this study, greatly simplifies the setup in which the test gas line is connected to an “analyser” reveals a more complicated gas sampling system in such a detector is currently more suitable for academic research, proof of concept evaluations and as an educational tool. Even in these proposed applications it is important that preliminary validation such as linearity is carried out prior to testing. As a case in point, early findings have shown that the Toxi-Rae Pro employing the formaldehyde electrochemical sensor (resolution: 0.01 ppm) did not perform as well as the methyl mercaptan sensor did in this study.

4. Conclusions
Through method validation (linearity) and differentiation of sample performance, the use of a commercial gas detector is shown to be a suitable analytical method for photocatalytic air purification of methyl mercaptan. The advantages such as low-cost, ease-of-use and datalogging capability make it an attractive alternative to existing gas chromatographic methods. Similar studies with other detectors/sensors would demonstrate wider application to other pollutant gases. Full validation with an interlaboratory study and comparison to existing standardized gas chromatographic methods would be necessary for use of such detectors in quality assurance and commercialization of photocatalytic materials. Nevertheless, the data generated in this study shows that gas detectors can have sufficient accuracy for use in academic photocatalytic air purification tests.

Notes and references
† Using supplied permeation tubes, the span gas calibration concentration is given by: \( C = E^*K_0/F^*1000 \) where \( C \) is the concentration in ppm, \( E \) is the emission rate of the component compound in the tube, \( K_0 \) is a constant converting emission rate from weight per minute to volume per minute and \( F \) is the dilution gas flow rate in L/min. In this study, for example, to deliver 3 ppm of methyl mercaptan calibration gas (\( E = 3144 \) ng/min, \( K_0 = 0.466 \)) the diluent flow rate is adjusted to 0.49 L/min as \( F = \frac{3144*0.466}{3.0*1000} \).
