Just Accepted

“Just Accepted” manuscripts have been peer-reviewed and accepted for publication. They are posted online prior to technical editing, formatting for publication and author proofing. The American Chemical Society provides “Just Accepted” as a free service to the research community to expedite the dissemination of scientific material as soon as possible after acceptance. “Just Accepted” manuscripts appear in full in PDF format accompanied by an HTML abstract. “Just Accepted” manuscripts have been fully peer reviewed, but should not be considered the official version of record. They are accessible to all readers and citable by the Digital Object Identifier (DOI®). “Just Accepted” is an optional service offered to authors. Therefore, the “Just Accepted” Web site may not include all articles that will be published in the journal. After a manuscript is technically edited and formatted, it will be removed from the “Just Accepted” Web site and published as an ASAP article. Note that technical editing may introduce minor changes to the manuscript text and/or graphics which could affect content, and all legal disclaimers and ethical guidelines that apply to the journal pertain. ACS cannot be held responsible for errors or consequences arising from the use of information contained in these “Just Accepted” manuscripts.
New Generation Electron Beam Resists: A Review

Anushka S. Gangnaik, Yordan M. Georgiev†, Justin D. Holmes*

Materials Chemistry and Analysis Group, Department of Chemistry and Tyndall National Institute, University College Cork, Cork, Ireland and AMBER@CRANN, Trinity College Dublin, Dublin 2, Ireland

ABSTRACT: Semiconductor industry has already entered sub-10 nm region, which has led to the development of cutting-edge fabrication tools. However, there are other factors that hinder the best outcome of these tools, such as the substrate and resist materials, pre- and post-fabrication processes, etc. Amongst the most lithography techniques, electron beam lithography (EBL) is the prime choice when a job requires dimensions lower than 10-20 nm, since it can easily achieve such critical dimensions in reasonable time and effort. When obtaining pattern features in single nanometer regime, the resist material properties play an important role in determining the size. With this agenda in mind, many resists have been developed over the years suitable for attaining required resolution in lesser EBL writing time. This review article addresses the recent advancements made in EBL resists technology. It first describes the different lithography process briefly and then progresses on to parameters affecting the EBL fabrications processes. EBL resists are then bifurcated into their "family types" depending on their chemical composition. Each family describes one or two examples of the new resists; and their chemical formulation, contrast-sensitivity values and their highest resolution are described. The review finally gives an account of various alternate next-generation lithography techniques, promising dimensions in the nanometer range.
1 INTRODUCTION

Nanotechnology is the art and science of shaping matter in such a way that resulting structures (nanostructures) have at least one dimension between 1 and 100 nm. It covers a large range of scientific fields from chemistry, physics, biology and engineering to nanofabrication, surface science and medicine. Nanotechnology research is also very diverse and includes nanodevice fabrication, molecular self-assembly techniques and generation of new materials. Nanotechnology has enabled us to achieve advanced, superior and powerful products used for the betterment of human life.

One of the most prominent applications of nanotechnology is in the semiconductor industry, due to the miniaturisation of complex circuitry in microelectronic devices. This scaling down of size has pushed the scale limit of integrated circuits to beyond sub-50 nm and hence demands for fabrication methods with superior performance. There are two fundamental approaches on the basis of which nanofabrication is currently carried out: Bottom-up and Top-down approaches. These two approaches can be applied individually or in combination. The top-down approach involves carving out nanostructures from bulk substrates and involves several processes, e.g. lithography combined with additive/subtractive processes of pattern transfer, such as thin film deposition, implantation, diffusion, etching, etc. Bottom-up approaches act in the reverse direction, i.e. the nanostructures are formed by starting from atomic/molecular elements, which are gradually assembled until the desired structure is obtained through processes such as self-assembly of molecules, nanoscaffolding, etc.

The top-down approach is still the prevailing technique in the micro- and nanoelectronics industry. Nanolithography plays a central role in this approach, where a stencil with the required pattern is created usually in a sacrificial layer called “resist”, deposited on the main working material, like silicon (Si). There are various nanolithography techniques including deep ultraviolet (DUV) lithography, electron beam lithography (EBL), soft lithography, nanoimprint lithography (NIL), X-ray lithography, photon beam lithography (PBL) or scanning probe lithography.

1.1 THE PHOTOLITHOGRAPHY PROCESS

Photolithography is the most commonly used lithographic processes. It uses light of various wavelengths to create desired patterns. Typically, a suitable base substrate is coated with a thin film of a polymeric substance called a ‘resist’. A photomask, usually made of ~80 nm thick patterned chromium metal layer deposited on a quartz plate, is held very closely or pressed against the resist-coated substrate and light of the desired wavelength is radiated on the mask for a certain time interval. The areas of the resist below the openings in the patterned chromium layer are exposed to the light and the irradiation brings about changes in the chemical structure of the underlying resist material. In most positive-acting resists, long polymer chains will break down into smaller components, whereas in negative-acting resists, polymer chains will crosslink on exposure to irradiation to form longer polymer chains. The substrate is then immersed in a specific solution called ‘developer’ and the exposed areas are selectively dissolved (positive) or remain insoluble (negative) in the solution. Subsequently, the substrate is ready for further processing, e.g. etching, metal deposition, etc.

Optical lithography is the most widely used patterning technique in the integrated circuit (IC) industry. During the past two decades, photolithography has matured and improved its capability to create very small features. However, with the ever-increasing demand for newer generation devices, the miniaturisation of device components has rapidly developed. Photolithography, due to its diffraction limits is unable to produce extremely small and densely populated features much below 50 nm. The diffraction effect from the mask openings and reflection effects within the resist, degenerate the quality of the obtained structures. Deep ultraviolet (DUV) lithography has enabled to achieve resolution down to sub-50 nm, by employing wavelengths of 193 and 248 nm. Large-scale integrated ICs are currently fabricated by multiple exposures with immersion DUV lithography, but then again the equipment required is very expensive. Techniques like extreme ultraviolet (EUV) and X-Ray lithography have also been developed, which use even shorter wavelengths than DUV, i.e. 13.5 and 10's nm (soft X-rays) down to 1Å (deep X-rays), respectively. However, these approaches require complex and very expensive instrumentation.
1.2 THE CHARGED PARTICLES LITHOGRAPHY

In order to overcome the shortcomings of photolithography, alternative lithography techniques have been developed that uses charged particles instead of photons to create patterns. Using charged particles such as electrons, ions, or protons allows both patterning and imaging of a substrate. Whilst photolithography involves ‘flood-type’ exposure through a mask, direct writing can be achieved with a narrow beam of charged particles. This lithographic approach is a mask-less method, wherein desired designs are generated on computer software and then directly written with the particle beam onto a substrate. The beam sequentially writes the pattern, exposing point by point at a time or one pixel per interval. A small beam size, down to 1-2 nm, can be achieved by fine focusing and adjusting the aperture through which the beam passes. Due to the nature of charged particles, unlike photolithography, diffraction issue do not interfere with patterning thus yielding sub-20 nm size features very conveniently.

The most extensively used charged particle techniques are the electron beam lithography (EBL) and ion beam lithography (IBL). As the names suggest, the beam in the EBL consists of high-energy electrons that are used to write the desired pattern, whereas in IBL they are high-energy ions. Amongst the two, EBL, like photolithography, is a resist-based lithography. The EBL resists are specially formulated to undergo chemical reactions once they are exposed to high-energy electrons. IBL, on the other hand, may be used both with and without resist, since ions are much heavier than electrons and can easily mill substrates like silicon (Si) or germanium (Ge), carving the desired pattern. Both techniques are thus capable of producing very small structures, since the beams can be finely focused. However, exposure of patterns pixel by pixel increases writing time, especially for complex patterns with high design densities. Therefore, the throughput of EBL and IBL is low and hence these techniques are mainly used in research and development (R&D) as well as in small volume production and in industry for photomask fabrication.

In summary, although photolithography, in particular the DUV lithography, is still the main technique used for mass production in the semiconductor industry, beam lithographies and especially EBL is becoming increasingly widespread and is the dominant nanolithography method used in academic and research environments due to its flexibility and mask-less nature, very high (sub-10 nm) resolution as well as maturity and affordability of equipment.

2 PARAMETERS OF ELECTRON BEAM RESISTS

The techniques hitherto discussed, all have a common component without which they would be futile processes, namely a resist. Resists are usually polymeric materials that can be deposited on most surfaces that are subjected to patterning e.g. with photolithography or EBL. Many new commercial resists have emerged lately with the aim of improving resolution limits of lithography. In the following section, new EBL resists introduced over the last 5-6 years shall be discussed in detail.

Generally, a thin layer of the resist, ranging from 20-25 nm up to a micrometre is spin coated onto a substrate. The resist are usually organic or inorganic polymers and can be broadly classified into two types with respect to their tones, i.e. positive or negative. The electron beam irradiates the resist in such a manner that after development the radiated portion will be eliminated (positive tone) or will persist (negative tone) on the substrate. The patterning resolution of a polymer resist depends on its chemical structure. Achieving the best possible resolution with both positive and negative EBL resists requires manipulation of many parameters.

2.1 Contrast and Sensitivity

Contrast and sensitivity are the primary characterisation factors to be taken into consideration when choosing any resist. Contrast is the property of a resist to differentiate between exposed and unexposed areas. This is in turn coupled with a property known as sensitivity, which defines the extent of alteration in the resist material with respect to the electron beam dose. An electron dose is usually expressed in \( \mu \text{C/cm}^2 \) and is the number of electrons/electric charge per unit area required to achieve the desired changes in a resist. Contrast and sensitivity together give rise to a contrast curve of a resist which is obtained by simply plotting the remaining resist thickness as a function of increasing electron beam dose. The plot shown in Figure 1 illustrates the contrast curves for a positive and negative resist. The plot shows the decrease (positive) or increase (negative) of the remaining resist thickness versus the exposure dose. According to the curve, the sensitivity is the dose \( D_{\text{ss}} \) at which the resist is completely developed (for a positive resist) or reaches the full initial resist
thickness (for a negative resist) and contrast is the slope of the curve.

![Figure 1. Typical contrast-sensitivity plots for positive and negative EBL resists](image)

Sensitivity and contrast are expressed by the equation:

\[
\gamma = \frac{1}{\log \frac{D_{100}}{D_0}}
\]  

where \(\gamma\) is the contrast value, \(D_0\) is the highest dose at which the resist is not yet affected by the electron irradiation (for a positive resist its thickness is still 100% of the original thickness and for a negative resist its thickness is still 0), whereas \(D_{100}\) is the minimum dose at which the resist has undergone a complete change of its chemical structure. Ideally, a resist must possess a high sensitivity and contrast. In reality however, an increase in one parameter will result in a decline of the other and vice versa. Hence, resists are often tuned to have a good balance of both parameters. Sensitivity of a resist varies with respect to resist type, electron energy, developer solvents and development conditions. Substrate materials to be patterned also play an important role.

2.2 Developer Solvents

Besides the resist properties, developer solvents, development time and temperature are among the most important factors that govern the contrast-sensitivity balance. Substrates, after the EBL exposure, are developed in solvents that separate the exposed from the unexposed resist. The resist-developer interdependency can immensely influence the contrast-sensitivity balance. Therefore, sensitivity and contrast are properties not only of the resist but rather of the certain couple resist-developer. For example, poly methylmethacrylate (PMMA) is the most well-established and extensively studied polymeric EBL resist. FTIR studies have shown that upon irradiation, PMMA chain-scission causes C=C bonds, which is soluble in the developer. Scheme 1 illustrates the irradiation induced reactions in PMMA. Other methyl acrylate resists have also shown to follow similar chain-scission path. Table 1 illustrates the effect on contrast, sensitivity and the surface roughness of PMMA resist having 950 K molecular weight (MW) by varying development conditions.

![Scheme 1. Schematic representation of the mechanism of electron beam irradiation-induced reactions in PMMA films](image)

### Table 1. Comparison of sensitivity, contrast and surface roughness of PMMA (MW 950 K) for different development condition obtained with 19 kV beam.

Table 1 shows that isopropyl alcohol (IPA) and methyl isobutyl ketone (MIBK) in a 3:1 ratio, which is the standard developer for PMMA, exhibits a higher sensitivity than pure IPA for all time intervals. Conversely, the contrast is the highest for PMMA developed in a single component developer, IPA, for 5 s and is higher than IPA:MIBK by a
difference of 3.3. Moreover, surface roughness of the exposed area has also been reduced upon moving from IPA:MIBK to pure IPA. These factors impact on the lithographic performance of PMMA, as demonstrated in Figure 2.

Figure 2(a) shows that the 50 nm gratings achieved by an electron dose of 180 µC/cm² at 19 keV exhibit poorly defined structures when developed with IPA:MIBK. With pure IPA, however, the 50 nm gratings are very well resolved although the sensitivity is reduced to 750 µC/cm². Reduced sensitivity but improved contrast is therefore achieved using IPA as a developer, as opposed to IPA:MIBK, for EBL lithography of PMMA resist.

![Figure 2](image)

2.3 Temperature

![Figure 3](image)

Figure 3 shows that the temperature of the developer has a considerable effect on the contrast-sensitivity of HSQ resist. As the temperature is raised from room temperature (20° C) to 50° C, the contrast is improved but at the cost of reduced sensitivity. The main reason for this is that warm developers are more effective in dissolving the resist molecules than the cold ones. Therefore, at room temperature the developer is not able to dissolve the resist areas that are partially exposed by forward- and backscattered electrons (only partially cross-
linked), leading to good sensitivity (less primary dose necessary to form a resist structure remaining on the substrate) but poor contrast. At elevated temperatures, however, the partially exposed resist is completely dissolved, which results in lower sensitivity (more primary dose necessary to form a resist structure remaining on the substrate) but higher contrast (better differentiation between exposed and unexposed or partially exposed resist).

In the case of a positive resist, the opposite effect is observed, i.e. cooler developer solutions have shown to improve the contrast immensely, however negatively affecting the sensitivity. Here the reason for this behaviour is again the same as with the negative resists but working in the opposite direction, since the electron exposure dissociates the molecular bonds in positive resists, causing scission of molecules, whereas it cross-links the molecular bonds in negative resists, causing networking of molecules. Therefore, at room temperature the developer is able to dissolve the partially exposed positive resist, leading to good sensitivity (less primary dose necessary to remove the resist from the substrate) but poor contrast. At low temperatures, however, the partially exposed positive resist is not dissolved by the developer, which results in lower sensitivity but higher contrast. Figure 4 illustrates the contrast curves of the positive resist SML at different voltages developed in a 7:3 ratio of IPA:water. Two developer temperatures were employed, i.e. room temperature and 0 °C. The plot shows that the sensitivity of the resist developed at 0 °C is reduced by 4 times compared to room temperature and the contrast is moderately increased (by approximately 1.6 times).

2.4 Auxiliary Factors

In this section supplementary important factors that contribute to resist profiling are briefly discussed. Technical restrictions arising from a particular lithography tool also contribute to the resolution of the resist. EBL systems are usually designed with voltages from 1 to 30 keV, for converted SEMs, and from 25 to 100 keV for dedicated systems. The sensitivity and resolution of a resist depends largely on the energy of the electron beam. For any resist, the sensitivity decreases when higher voltages are employed whereas the contrast (resolution) improves. The main reason for this is that slow electrons interact more readily with solids and hence they expose the resist much more efficiently than fast electrons. Therefore, resists are more sensitive to irradiation with low-energy electrons than with high-energy electrons. This is clearly seen in the Bethe equation, which describes the mean energy loss per distance of fast non-relativistic electrons in solids:

$$\frac{dE}{dx} = \frac{2\pi\rho Z_{eff} A_{eff}}{E A_{eff}} \ln\left(\frac{1 + \beta}{\beta}\right),$$

where \(e\) is the electric charge of an electron, \(E\) is the electron energy, \(\rho_{eff}\), \(Z_{eff}\), and \(A_{eff}\) are the effective mass density, atomic number, atomic weight, and mean ionisation potential of the target, respectively. Since the energy loss of the electrons is approximately proportional to \(E^2\), the higher the initial energy of the electrons, the less efficient is the energy deposition in the resist.

Another important fact is that the electrons are light particles and they are easily scattered in solids. Therefore, when a resist is exposed to an electron beam, it is irradiated by the primary electrons on their first passage through the resist (forward scattered electrons) as well as by electrons that have already reached the substrate and are scattered back into the resist (backscattered electrons). In addition, secondary electrons generated by both forward and backscattered electrons also irradiate the resist. These phenomena leads to the fact that the resist is exposed not only in the intended areas but also in wide adjacent regions, causing a distortion of the designed pattern known as a "proximity effect". At low energies, e.g. 10 keV or less, forward scattering is high, causing significant widening of the electron beam. In addition, backscattered electrons have a short range and are confined around the point of incidence of the electron beam causing substantial exposure of the resist. Therefore, at low electron energies the
proximity effect is relatively high and may lead to considerable distortion of the exposed pattern. Conversely, at high electron energies, e.g. 100 kV, the proximity effect is relatively less pronounced and the exposed pattern is usually closer to the original design.

Thus, for low resolution and large structures, i.e. micron sizes and above, low energy beams can be used to reduce the exposure time. For critical high-resolution patterns, however, high energies are needed. For instance, Figure 5 illustrates a germanium-on-insulator (GeOI) test device structure designed and patterned to measure the resistance across a nanowire having a width of 20 nm. This device was fabricated at two different exposures: the nanowires were fabricated at 10 keV with a fine electron beam whereas the contact pads were exposed at 1 keV with a large electron beam. At 10 keV the writing time for the large contact pads would have been approximately 15 minutes, however due to the lower voltage and the larger beam used the writing time was reduced to 1 minute.

Resist roughness is influenced by various factors like molecular weight of the polymer, the phase separation and polymer aggregation it undergoes in a developer solvent and irradiation dose. A bell-shaped curve of the root mean square roughness versus electron beam dose has been observed for positive resists and has been explained as a result of different rate of phase separation occurring at various doses.\textsuperscript{14,8} Figure 6 is an example of the bell-shaped roughness curve of PMMA resist developed in 1:4 MIBK:IPA. The roughness can, however, be controlled by appropriate choice of developer solvent for a resist.

![Figure 6](image)

Figure 6. Experimental contrast curve and corresponding RMS roughness, for 2300 k PMMA resist using dip development at 25 °C for 30 s with 1:4 MIBK:IPA exposed with 50 kV beam.\textsuperscript{14}

Similar dependence of the root mean square roughness versus electron beam dose has been observed also for negative resists.\textsuperscript{15,16} Georgiev et al. have found that HSQ roughness depends on the developer concentration (in this case tetramethylammonium hydroxide, TMAH) and especially on the pre-exposure bake temperature. It has been shown that a combination of a strong developer with low baking temperature delivers low HSQ roughness and is favourable for achieving high resolution with this resist. Moreover, drying processes after resist development and rinsing can also have a significant impact on resist roughness. For example, supercritical CO\textsubscript{2} drying has been shown to significantly reduce HSQ roughness and improve stability of high aspect ratio lithographic structures.\textsuperscript{17}

International technology roadmaps for semiconductors (ITRS) stated that the LER and LWR should be less than 8% of the critical dimension, since they can directly influence the device performance.\textsuperscript{18} With the aggressively reduced critical dimension in the current and future
semiconductor technology nodes, this requirement is a significant challenge to resist performance. Roughness is thus becoming an important leg in nanolithography.

3 EBL RESIST FAMILIES

EBL is a direct-write process and due to the lightweight nature of the electrons, the beam cannot engrave typically used substrate materials. Resists are thus an integral part of an EBL process. The resist pattern produces a stencil on the substrate, which can be transferred into the substrate with further fabrication processes. Over the years, many new resists have been formulated to fulfill various micro- and nanofabrication demands. Traditional resists like PMMA, ZEP and HSQ are the most commonly used ones due to their superior lithographic outputs. This section will highlight new classes of EBL resists that have been introduced during the past 5-6 years.

While defining electron resists, the aforementioned words PMMA, ZEP and HSQ appear regularly in the literature. Most of the literature reports on resists, irrespective of resist tones, often consider these resists as standard for resolution comparison with new resists. HSQ (Dow Corning) is the commercially available resist that has provided the highest resolution EBL structures down to sub-5 nm. HSQ is an inorganic material belonging to the spherodiloxane family, with a low dielectric constant (2.8). HSQ’s high-resolution capability, ease of imaging post-exposure and etch resistance are its prominent features. However, the resist suffers from several drawbacks, such as a very limited shelf life of up to 6 months and a necessity to be stored at a temperature below 5 °C, thus requiring a high standard of maintenance. HSQ is extremely sensitive to moisture and hence the interval between spin casting and exposure must be as minimal as possible to avoid unsolicited crosslinking of polymer molecules. From the lithography point of view, the resist suffers a relatively low sensitivity, \( e.g. \) an electron dose of between 900-1000 \( \mu \text{C/cm}^2 \) is required to generate a 50 nm wide line on Si at 10 kV, which eventually increases the writing time in comparison with PMMA (~330 \( \mu \text{C/cm}^2 \)) and especially ZEP (~120 \( \mu \text{C/cm}^2 \)). Thus, even though HSQ exhibits commendable lithographic qualities, it is still a difficult resist to handle.

PMMA is a well-established positive resist having a good balance of sensitivity, contrast and roughness. Therefore, it is by far the most widely utilised EBL resist. PMMA with different molecular weights can be used in various applications involving EBL fabrication. Sub-10 nm resolution structures have been demonstrated with PMMA using high beam voltages and cold temperature developments, thus requiring higher electron beam doses. The positive resist ZEP was developed around the end of 1980's. Early studies showed its commendable resolution, better etch durability and sensitivity improvement (one order of magnitude) in comparison to PMMA. However, over the last couple of years the commercial value of ZEP has risen by tenfold in Europe making it tremendously more expensive than PMMA.

Many new resists have emerged in the past few years. Other than their lithographic perspectives, aspects such as cost, shelf life, perilousness and compatibility with industrial semiconductor processes need to be taken into account. Resists are broadly classified into two divisions, positive and negative, depending on their reaction upon e-beam radiation. However, based on their chemical structures, they can be further classified into families, irrespective of their tones.

3.1 Chemically Amplified Resists (CARS)

A family of resists known as chemically amplified resists (CARS) emerged in the 1980’s as powerful lithographic materials due to their supreme sensitivity and resolution. These resists were initially proposed and developed by IBM as photoresists but are now also regularly used for EBL. They are basically a blend of an acid reactive polymer, such as an epoxy group-based polymer, and a photo-acid generator (PAG). They are also formulated in the two tones of the resists. Upon electron irradiation, the photo-acid is released which catalyses further reactions without an additional electron dose, thus enhancing sensitivity. The substrate is then baked after exposure in order for the released photo-acid to catalyse the resist matrix. However, as device miniaturisation has continued, several factors have affected the resolution of CARS. Firstly, the non-uniform acid diffusion and migration within the resist film during post-exposure baking limits the critical resolution of CARS. Secondly, as a result of acid diffusion, roughness in patterned structures arises. Thus, controlling acid diffusion is a priority to acquire high-resolution feature sizes from CARS. One of the methods used to overcome this problem was to bond a PAG unit to the polymer sidechain, rather than blending the PAG with the polymer.
several polymer-bound PAG CARS have been developed over the last few years.

Polymer-bound PAG resists are therefore usually a merger of complex polymers. Recently, such a negative tone CAR comprising of glycidyl methacrylate (GMA), methyl methacrylate (MMA) and triphenylsulphonium salts methacrylate (TPSMA) was developed for EBL and was compared with a polymer blended PAG CARS for sensitivity and contrast.\textsuperscript{32} Firstly, the two polymers were polymerised together to give the product poly (GMA-co-MMA) which was further polymerised with the PAG to give poly (GMA-co-MMA-co-TPSMA) powder (Avg. Mol. wt. = 23,800 g/mol). The resist solution was prepared by dissolving the powder in dimethylformamide (DMF) or propylene glycol monomethyl ether acetate (PGMEA). Their sensitivity, lithographic performance and etch resistance were evaluated in the study. The contrast curve of the first CAR revealed a sensitivity of 300 \( \mu \text{C/cm}^2 \) without any post-exposure bake. The sensitivity of the second polymer mixture, poly (GMA-co-MMA-co-TPSMA), was measured as 125 \( \mu \text{C/cm}^2 \) with a 100 kV beam without post-exposure bake, which further reduced to 70 \( \mu \text{C/cm}^2 \) by post-exposure baking at 80 °C for 60 s. The resists were developed in a mild 7:3 ratio of IPA:water developer solution for 1 min followed by rinsing in deionised (DI) water. The smallest feature size that was acquired from the resist was a 15 nm line with a 1:15 pitch size, as illustrated in Figure 7(a). Dense grating of 20 nm lines using a 1:1 pitch size was also obtained and shown in Figure 7(b). However, post-exposure bake accelerated acid diffusion in the resist, thus unfavourably affecting the line edge roughness (LER), as shown in Figure 7 (c). The post-exposure bake can however be excluded, hence cutting down a process step at the expense of lower sensitivity. The RIE etch rate of the resist was determined to be 40 nm/min with CF\textsubscript{4} gas chemistry.

Positive tone CARS have also been employed and one of them recently used for EBL is 40TX. Such resists, when employed alone, produced an almost insoluble top layer due to the reaction between photo-acid vaporisation and vapour contaminants.\textsuperscript{33-34} Therefore, in a study a protective coat was spun on the CA resist which was comprised of acidic poly (3,4-ethylenedioxythiophene) poly(styrene-sulfonate) (PEDOT:PSS).\textsuperscript{35} Contrast curves were generated for the resist at 20 keV using the standard developer AZ\textsuperscript{®} 726MIF in various dilutions with DI water. The high sensitivity range of this resist lies between 7-10 \( \mu \text{C/cm}^2 \) and the contrast varies from 7-14. The effects of various developer dilutions on contrast-sensitivity values are given in Table 2. The critical dimension (CD) of the resist in this study was measured after a complete lift-off process, hence the CD values were between 80 to 110 nm as shown in Table 1.2. Gold nano-gratings, approximately 90 nm in width and 70 nm apart, were fabricated using this resist, as illustrated in the SEM image shown in Figure 8. The purpose of the study was to fabricate robust structures with this CAR, as there were no significant linewidth or sensitivity variations observed even when the samples were stored for 24 h in vacuum or air.\textsuperscript{35}

Table 2. Contrast and sensitivity values of 40XT positive CARS for different development parameters.\textsuperscript{38}

3.2 Non-CARS

Whilst CARS have demonstrated extremely high sensitivity, the LER and line width roughness (LWR) constrain the achievement of sub-20 nm feature size with them, as acid diffusion in the resist is uncontrolled at this scale. To counter this effect, advanced classes of resists are being formulated which are directly sensitive to radiation and do not contain a PAG moiety. In order to increase the irradiation sensitivity, a radiation sensitive group must be incorporated into the polymer unit. Such resists are known as non-chemically amplified resists (n-CARS). Sulphonium salts have been known to be sensitive to UV and electron beam radiations and can be incorporated into polymer units. In a recent study, a copolymer of (4-(methacryloyloxy) phenyl) dimethylsulphonium triflate (MAPDST), the radiation sensitive group, and methyl methacrylate (MMA) was synthesised (MAPDST–MMA). This copolymer was dissolved in methanol to give a negative tone resist solution. The copolymer resist coated substrates were exposed to electrons at 20 kV and were subjected to post-exposure bake at 100 °C for 120 s, followed by development in a 0.022 N TMAH solution. The customary characteristics of this resist were evaluated. The exceptionally high sensitivity of 2.06 \( \mu \text{C/cm}^2 \), in contrast to the popular negative HSQ resist, which requires a dose close to 2000 \( \mu \text{C/cm}^2 \) to pattern lines of similar width and spacing. The gratings also exhibited a reasonable LER of between 1.8 to 2.2 nm.

It was demonstrated by FTIR and XPS characterisation that irradiation of the resist strongly reduces triflate and COO group signals, whereas the S-C bonding belonging to the phenyl group remains resistant to the exposure. Since the unexposed resist remains polar because of its ionic character (Figure 9 (c)), it can readily solubilise in the developer. On the other hand, upon irradiation
the anionic counter ions (CFSO$_3^-$) result in the formation of Ar-S$^-$-(CH$_3$)$_2$ groups, which convert to Ar-S-CH$_3$ during the post-bake, losing thier ionic character. Due to its non-ionic nature, the exposed resist was intact when dipped in developer solution. Hence, the addition of a highly radiation-sensitive sulphonium group to the polymer unit enhances the sensitivity of the resist tremendously. Structures as fine as 20 nm could be easily resolved with this resist. LER was found to be 1.8±0.1 nm of MAPDST-MMA resist. Thus, this resist is a good candidate for future high resolution EBL due to its high sensitivity and contrast and ability to generate low LER structures. The etch ratio of the MAPDST-copolymer to SiO$_2$ with CHF$_3$/O$_2$ gases (22.5/2/5 sccm, 80 mTorr, 150 W RF power for 60 s) was found to be 0.36:1.

However, in another study, a methacrylate based n-CARS was formulated that exhibited a very high sensitivity. The resist was created by free radical polymerisation of 2-hydroxyethyl methacrylate (HEMA) and aminoethyl methacrylate (AEM) to give the product poly(2-hydroxyethyl methacrylate-co-2-methacrylamido-ethyl methacrylate) (P(HEMA-co-MAAEMA)). Its processing parameters and etch durability as a mask on Si were assessed. The contrast curves of the resist showed an extremely high sensitivity of about 0.89 $\mu$C/cm$^2$ and a contrast of 1.2 (figure 10(a), which is comparable to the commercially available low-contrast negative EBL resists such as mr-EBL 6000 and AR-N 7720. The contrast curve was obtained by developing a 1.1 $\mu$m thick film in methanol developer. However, as shown in the AFM image and its corresponding cross-section in figure 10(b), the resist demonstrates a low resolution up to 125 nm. The authors, nevertheless, suggest that the resolution can be improved by modifying the development process, using thinner resist films or by modifying the accelerating voltages. Etch resistance of this resist was studied for RIE (SF$_6$), as well as, for wet chemistry with in HNA (HF: nitric acid: acetic acid) solution. The resist showed good resistance to the wet etch process and where the resist to silicon selectivity was 1:9.4 (etch rate of resist was ~15-20 nm/min). However, the resist performed poorly when subjected to dry etch since the resist to silicon etch rate ratio was found to be 1:2 and the etch rate of the resist was 225-275 nm/min.

3.3 Fullerene Derivatives Resists

Buckminsterfullerene (hence after referred as fullerene), C$_{60}$, is an allotrope of carbon containing 60 C-atoms to form a spherically shaped unit. Fullerene’s potential as a negative tone EBL resist was first recognised by Tada et al. due to its reactivity towards UV light. C$_{60}$ has small diameter, of around 0.7 nm, making it ideal for high-resolution lithography. Tada et al. showed that electron beam irradiation caused the solubility of a C$_{60}$ film to reduce in a toluene developer, thus allowing it to be used as a negative-tone resist. However, C$_{60}$ has a very low sensitivity of about 12 mC/cm$^2$ and requires preparation via vacuum sublimation. Nevertheless, in the last few years, new types of polymer-bound fullerene derivative resists have been synthesized, which can be spin coated onto substrates. Two such resists, C$_{60}$-containing poly (p-tert-butoxystyrene) and C$_{60}$-
containing poly (p-tert-butoxycarbonyloxystyrene), have been developed for photolithography.\(^{46}\) In the case of EBL resists, two of the fullerene derivatives developed in recent years, with different polymer chains, shall be discussed in the section below.

The first study involved the blending of two polymers, poly (p-chloromethylstyrene) (PCMS) and poly (hydrostyrene) (PHS), in which the \(C_{60}\) moiety was incorporated.\(^{47}\) The main motivation behind using the PCMS polymer was its high electron sensitivity, whereas \(C_{60}\) alone has a tremendously low sensitivity of approximately \(10^4 \mu C/cm^2\).\(^{43,48}\) The PHS was used because the hydroxyl group aids in the adhesion of the \(C_{60}\) derivative resist to a substrate. Various blends of the three units consisting of different weight fraction of \(C_{60}\) have been produced, as shown in Table 3.

**Table 3. Blends of PCMS and PHS polymers consisting of different weight fraction of \(C_{60}\) for preparing the resists.\(^{47}\)**

The resist-coated substrates were exposed to electrons at 100 kV and developed with toluene or acetone to evaluate their lithographic performance. Figure 11 illustrates the reaction mechanism of a \(C_{60}\) derivative resist upon electron beam radiation. The \(C_{60}\) derivative shown in Figure 10 is coded as \(C_{60}-(\text{PCMS}_{x}\text{HS})_2\) where \(x = 14, 31\) or 46, thus varying the weight fraction of \(C_{60}\), according to Table 3. The developer used was acetone however strong aggregations of \(C_{60}\) moieties were found, which resulted into swelling and deformation of the structures. Figure 12 shows an SEM image of 50 nm gratings, the minimum resolution obtained with \(C_{60}-(\text{PCMS}_{46}\text{HS})_2\), at a dose of 286 \(\mu C/cm^2\) and a LER of \(-7\) nm.

The \(C_{60}-(\text{PCMS}_{46}\text{HS})_2\) resist gave the best result in terms of resolutions amongst the other compositions given in Table 3. Hence, it was concluded that \(C_{60}\) could be utilised as negative tone EBL resists. The sensitivity of the \(C_{60}\) moiety was increased by 3 orders of magnitude with the addition of the copolymers, achieving high-resolution structures down to 50 nm in each case.

In the second recent study, three phenol-based fullerene negative tone resists have been presented for next generation electron beam lithography.\(^{49}\) The resist was not only a fullerene derivate, but also a CAR consisting of a crosslinker and a PAG component. The first fullerene derivative prepared consisted of phenolic methanofullerene (IM-MFP12-3). The other two resists consisted of tertiary butoxyxcarbonyl (tBOC) protecting groups, however they differed in that one had a longer side chain (IM-MFP12-8) than the other (IM-MFP12-2). The resists were prepared by dissolving the fullerene derivative, epoxy crosslinker and...
triphenylsulphonium hexafluoroantimonate PAG in propylene glycol monomethyl ether (PGME), with a 10-20 g/L concentration. They were then mixed in one part fullerene derivative, two parts crosslinker and one part of the PAG and spin-coated onto Si substrates. The chemical structure of the three fullerene derivatives along with their contrast curves can be seen in Figure 13.

![Chemical structures and contrast curves](image)

Figure 13. Chemical structures of (a) (3-phenol-1-propyl malonate)-methano-[60] fullerene, (b) (t-butoxycarbonyl malonate)-methano-[60] fullerene and (c) [3-(4 butoxycarbonyl) phenyl-1-propyl malonate]-methano-[60] fullerene and (d) contrast curves for the three resist derivatives.

The Si substrates were post-exposure baked at 90 °C followed by dip development in 1:1 monochlorobenzene (MBC) and IPA. Figure 13(d) shows the calculated contrast curves of the three resists and their sensitivity (contrast in brackets): 93 µC/cm² (1.8), 43 µC/cm² (1.3) and 32µC/cm² (1.0) for IM-MFP12-2, 3 IM-MFP12-8 and IM-MFP12-3, respectively. Thus the enhanced sensitivity, amongst the tBOC-protected material, of IM-MFP12-8 was attributed to the higher flexibility of longer polymer chains helping to improve crosslinking. Long chains have previously been reported to enhance acid diffusion, which is evident in this study.

![SEM images of dense single pixel features](image)

Figure 14. SEM images of dense single pixel features of IM-MFP12-8 resist, with the top row developed without post-exposure bake and the bottom row with 90 °C post-exposure bake. The pitches are 48 nm for (a) and (c); and 46 nm for (b) and (d) with their corresponding LWR.

Figure 14 illustrates the SEM images of single pixel gratings exposed on IM-MFP12-8 resist developed with 1:1 MBC:IPA. The linewidth observed for the gratings lies between 13-15 nm; exposed at 30 kV within a dose range of between 240-350 pC/cm². From the SEM images shown in Figure 14, LWR is higher for exposures developed without the post-exposure bake, thus indicating the requirement of post-exposure bake for the complete development of partially exposed resists for smoothing the LWR. A new negative phenol-based fullerene resist was conclusively presented in this study. The resist offered high sensitivity as well as a high resolution at low exposure doses as compared to the traditional high resolution HSQ resist. The ICP etch rate of IM-MFP12-8 was revealed to be 0.97 nm/s for SF₆/CHF₃ chemistry.

A positive tone fullerene derivative resist containing the acid labile groups tert-butyl acetate (tBAC) and (tBOC), has also been reported in literature. The sensitivity of the resist was found to lie in the range...
of 100-150 \( \mu C/cm^2 \) and isolated lines as small as 20 nm were successfully patterned. Thus, fullerene comprising materials have emerged as a new high-resolution class of resists.

3.4 Methacrylate Bases Resists

PMMA was the first resist of the methacrylate family and also the earliest EBL resist to be developed.\(^5^2\) This family of resists consist of a methacrylate backbone (CH\(_2\)CH\(_2\)CO\(_2\)CH\(_3\)) and are usually used as positive resists. However, upon elevating the electron dose the resist tone can be reversed into negative. PMMA is still regarded as the standard high-resolution resist and is the most widely used EBL resist. Lines as small as sub-5 nm have been resolved in PMMA by megasonic-assisted development\(^5^3\) or cold temperature.\(^5^4\) The other renowned resist of the same family is ZEP, which is a 1:1 copolymer of \( \alpha \)-chloro methacrylate and methyl styrene. The high sensitivity and etch durability, as well as the stability of this resist are prominent.\(^1^9, 2^8\)

Both the resists mentioned can be commonly developed in organic solvents such as MIBK, xylene based, amyl acetate, hexyle acetates and IPA:DI. Methacrylate-based resists offer good lithographic outcomes with ease of handling and hence both compounds have established themselves as mainstay electron beam resists.

During the last 5 years, two new resists with a methacrylate backbone have been reported: SML (EM Resist Ltd., United Kingdom) and chemically semi-amplified resist 62 (CSAR 62) (Allresist GmbH, Germany). The complete chemical structures of both these resists have been withheld, however the presence of a methacrylate group in SML and CSAR 62 has been reported.\(^1^0, 5^6\) CSAR 62 is a CAR consisting of the copolymer of \( \alpha \)-chloro methacrylate and methyl styrene in anisole, much like ZEP. However, unlike ZEP this resist includes additives to enhance its sensitivity, hence semi-chemically amplified.\(^3^5\) In a very initial study of CSAR 62, its parameters have been compared with those of ZEP and PMMA resists. For the contrast-sensitivity measurement, CSAR was developed using amyl acetate, which is the standard ZED N50 developer of a ZEP resist, o-xylene as well as using a combination of both solvents. The contrast curves plots generated at 100 kV under various conditions are illustrated in Figure 15.

Developing CSAR 62 with amyl acetate gave the highest contrast value of 5.2, as seen in Figure 15(b), however a large amount of resist residues were observed even after the clearance dose. On the other hand, the use of o-xylene developer reduced the residues but at the expense of contrast. The o-xylene dip after developing in amyl acetate gave a contrast (\( \gamma \)) and sensitivity (S) very similar to that of ZEP resist (\( \gamma_{ZEP} = 4.18 \), \( S_{ZEP} = 180 \mu C/cm^2 \) and \( \gamma_{CSAR62} = 4.77 \), \( S_{CSAR62} = 172 \mu C/cm^2 \)). The ultimate resolution of this resist was presented by another group using a 180 nm thick CSAR 62 resist where lines approximately 10 nm wide were resolved with a pitch of 100 nm, as evident in Figure 15.\(^5^7\) They also studied the etch rate of the resist with CF\(_4\)/O\(_2\) plasma, and an etch rate of 100 nm/min was revealed.

![Figure 15](image-url)
SML is also an organic, positive toned EBL resist. Initial works on this resist involve lithographic comparisons with PMMA and ZEP resists. It was found in a study that SML shows the best contrast-sensitivity trade-off with 7:3 IPA:DI water developer, like PMMA. Contrast curves of 300 nm thick SML resist obtained at 10 kV voltage, in comparison with those of PMMA and ZEP resists, are shown in Figure 17. It is to be noted that ZEP resist was developed in ZED-N50 developer and hence, gave a very high sensitivity of 21 µC/cm². It is apparent from Figure 17 that the sensitivity of SML is poorest amongst the three. However, it shows a very high contrast of 12, which is similar or even slightly higher than that of the high-resolution PMMA and ZEP resists.

Lithographic evaluation of the resist shows that high resolution could be achieved in SML with ~15 nm half pitch (Figure 18 (a)). The smallest linewidth resolved in SML is 5 nm and that in ZEP is 7 nm, which are till date the smallest features resolved in both the resists (Figures 18 (d) and (e)). The SML resist also exhibits efficient single layer metal lift-off property. FTIR characterizations have shown that the structural changes occurring in SML polymer after electron exposure are similar to that of PMMA and ZEP resist. The FTIR evaluations revealed that SML is a methyl acrylate based resist and thus, the structural changes upon electron irradiation is bound to be similar such as, increase in unsaturation and alteration in acrylate groups in SML and ZEP polymer chain after electron beam exposure were also revealed. The etching characteristic was compared to that of ZEP with SF₆/C₄F₈ gases chemistry. The initial etch rate of SML was found to be 17 nm/min for 60 s (the one of ZEP was 27 nm/min), and as the etch time increased, the etch rate increased gradually. However, the increased etch rate was comparable to that of ZEP resist. Since, ZEP is also well known for its high etch resistance, it can be said that SML is also a very good candidate as a hardmask during dry etching.

Acknowledging the high sensitivity and etch resistance of ZEP resist, a group developed a range of positive resists containing acrylic, chlorine containing monomer (acrylate A) and an acrylic monomer having aromatic side-groups (acrylate B). Copolymers of different compositions of acrylate A and B were synthesized and their lithographic quality was evaluated comparing to that of ZEP and PMMA. Table 4 describes the clearance dose, contrasts as well as the molecular weights of the different copolymers. The mass fraction of acrylate A ranges from 37 to 63 % in the
different copolymers. Evidently, the most sensitive
resist is ZEP and Copolymer 5 has similar sensitivity
with 30 kV electron beam. The sensitivity is seen to
be dependent on the mass fraction of acrylate A, i.e.
the clearance dose increases as the mass fractions
differs away from 40 wt.%. RIE etch tests of
Copolymer 5 revealed its etch resistance similar to
that of ZEP. Lithographic evaluation showed that
Copolymers 4 and 5 can produce nanometre sized
features down to 29 nm. The pinnacle resolution
was observed with Copolymer 4 as seen in Figure 19
(a). Figure 19 (b) shows Ti/Au 35 nm gratings
attained by lift-off method from a 100 nm thick
copolymer 5 (mr-Pos EBR) resist pattern.

Table 4. Molecular weight distributions of the
investigated resist materials and the sensitivity
and contrast data obtained at 30 kV acceleration
voltage.

3.5 Inorganic Resists

In comparison to organic resists, inorganic resists
generally possess higher contrast and better etch
resistance due to their chemical structure, but
invariably suffer a reduced sensitivity. The most
efficient resist, which has stanchly maintained its
high performance, is HSQ. HSQ is the smallest
member of the polyhedral oligosilsesquioxane
(POSS, trademarked by Hybrid Plastics) family, and
has a cubic structure (HSiO₃/2). On electron beam
exposure, the cubic HSQ molecules open and cross-
link, forming network structures. HSQ has
demonstrated a linewidth resolution of 7 nm, with a
pitch size of 14 nm, at a dose of nearly 1 mC/cm
(30 kV) and approximately 5 nm width with 40 nm
pitch (10 kV). 6 nm isolated lines and 7 nm dense
lines at doses of 5.5 and 33 mC/cm², respectively (100
kV), have also been reported previously. Nevertheless, due to its sensitivity issues and short
shelf-life, HSQ is often troublesome to work with.
Therefore, newer inorganic resists with silsesquioxane moieties and others containing metal
fragments have emerged.
In 2007 two negative, inorganic resists consisting of hafnium and zirconium oxide sulphates, known as HafSOx and ZircSOx, respectively, were reported.64 These materials are atomically very dense thus sensitizing the resists and due to their metallic nature they can be good candidates during ion etches.65 Resist solutions were prepared by combining HfOCl₂(aq) or ZrOCl₂(aq) with a mixture of H₂SO₄, H₂O, and 18 MΩ purified water to give metal:sulphate ratios of 1:0.5 and 1:0.7. The resists were spin-coated onto Si to achieve 35 nm thin films. The contrast curves and high-resolution performance of the resists were evaluated using 30 kV. Figure 18 presents the contrasts curves of the two metal sulphate resist developed with TMAH (HfOCl₂ = 90 s and ZrOCl₂ = 240 s). Figure 18(a) shows the contrast curves for HafSOx and ZircSOx having a metal:sulphate ratio of 1:0.55 and 1:0.5, respectively. The sensitivity of HafSOx was determined to be 21 µC/cm² with a contrast of 2.5, whereas that of ZircSOx was 7.6 µC/cm² with a contrast of 2.6. For an inorganic resist with no chemical amplification the sensitivity of both the resists is praiseworthy. Figure 20(b) shows a contrast-sensitivity plot of HafSOx and ZircSOx having a metal:sulphate ratio of 1:0.7. The sensitivity can be observed to decrease by a factor of 36 relative to its lower sulphate formulation, but with an improving contrast value of up to 5.2. In this study the sensitivity of the resist was correlated to the electron density of the resist polymer. The electron density was measured from the critical angle X-ray reflectivity measurements and was found to be 1.9 mol e⁻/cm³ for HafSOx and 1.5 mol e⁻/cm³ for ZircSOx, and for comparison 0.64 mol e⁻/cm³ for PMMA. The Bethe equation (2) states that the stopping power for an electron in a solid is directly proportional to the electron density of the solid Nₑ = N₀Zₑeff/Aₑeff, where N₀ is the Avogadro’s number.66 Thus, from the electron densities values measured, the new resists were observed to absorb the energy of the incident electrons more effectively than PMMA. This, in turn, will improve their sensitivity as compared to PMMA. In addition, the unwanted exposure of the resists due to the backward scattering of the incident electrons will also be reduced. The reaction mechanism of HafSOx correlated to its chemistry was shown by a group by energy-dispersive X-ray spectroscopy.67 The pre-bake treatment of HafSOx drives to densification of HafSOx thin film. Upon exposure to electron beam, the peroxide moiety is decomposed inducing condensation reactions that makes the resist insoluble in the developer solution (25% TMAH).

During development, the mobile sulphate species is replaced by -OH, which prepares for additional insolubleness of the resist.

The resolution of ZircSOx resist was evaluated by exposing line patterns on Si. The highest resolution achieved was a 16 nm isolated line, from a 1:0.5 ratio of ZircSOx and sulphate as shown in Figure 21(a), as well as a dense grating with line widths of 28 nm and a period of 100 nm, as shown in Figure 21(b). Isolated and dense gratings with 1:0.7 ratio of ZircSOx and sulphate are illustrated in Figures 21(c) and (d), respectively. The reaction mechanism of this resist during exposure is believed to be similar to that of HafSOx.67,68 The obvious difference between the two types of gratings is the LER, which appears higher for structures prepared with the 1:0.5 resist mixtures. The 3σ line width roughness values calculated for isolated and dense lines were 3.4 and 6.4 nm, respectively. In comparison, the 3σ values with the 1:0.7 resist mixtures were 1.9 nm for an isolated line and 2.1 nm for a dense grating. For the line shown in Figure 19(a), a dose of 112 µC/cm² was required, whereas the isolated line shown Figure 21(c) was achieved with a dose of 999 µC/cm². Thus, by increasing the sulphate concentration the quality of the structures is improved, but at the cost of reduced sensitivity. The etch rates of HafSOx and ZircSOx were determined as 2.2 nm/min and 2.9 nm/min respectively, by reactive CHF₃ plasma etching.
Thus, these resists exhibit high-resolution structures and high sensitivity comparable to that of several positive resists\textsuperscript{\textdegree} with lower roughness values and a good etch durability. Significantly, the sensitivity of these resists is very high when compared to HSQ.

Most of the non-organic resists are characterised by high etch resistance and also offer good resolution. In the following contribution, a spin-on hybrid resist system is exhibited, which on electron beam radiation turns onto an inorganic alumina, i.e. a hardmask.\textsuperscript{\textdegree} Tests showed etch selectivity towards Si in excess of 100:1, which is only comparable to that of metallic hardmasks. The resist is referred to as PhSiAl, abbreviation of Phenyl Silane and Aluminium-tri-sec-butoxide. It was synthesized by a sol-gel method by continuously stirring aluminium-tri-sec-butoxide (97%, Aldrich) with acetic acid in ratio of 1:0.05. After 1 h, 20% trimethoxyphenylsilane (≥95.0%, Aldrich) was added to it and stirred at 80 °C. The resulting solution was spun on Si substrates, variably diluted with ethanol to give resist film thicknesses from 30 nm to 1 µm. Contrast curves were not available for the resist, but the optimum dose mentioned for this resist is 800 µC/cm\^2 at 30 kV for dose matrix experiments\textsuperscript{\textdegree}, indicating that the resist sensitivity is in the vicinity of HSQ sensitivity. Depending on the choice of developer, when developed in buffered oxide etch (BOE) it can be a positive resist, whereas when developed in HCl and IPA mixture, it can act as a negative resist. The structural changes in the resist film after irradiation was determined by FTIR measurements on resist films exposed to UV light and X-rays, illustrated in Figure 22.\textsuperscript{\textdegree}

It is seen from the FTIR plot in Figure 22 that on exposure, the aromatic rings in the resist are shrivelled after exposure, confirming the degradation of organic network. Rise of the peaks near 3400 cm\^-1 confirms hydrolysis reaction of alkoxides, which happens due to increase in inorganic network. It is also confirmed by the Si-O-Si and Al-O-Al absorptions visible in the plot.\textsuperscript{\textdegree}

Lithographic assessments were carried out at 3 kV and evince very high resolution structures as seen in Figure 23. Figure 23 (a) shows array of diminutive resist gratings and an inset showing the 20 nm dimension of one of the lines and the highest resolution reported in this article is 11 nm grating. Similar structures were dry etched into Si by using SF\textsubscript{6}, C\textsubscript{4}F\textsubscript{8} and Ar gas mixture\textsuperscript{\textdegree} and the resist etch rate was found to be 2.67 nm/min with this gas mixture. Figure 23 (b), (c) and (d) show SEM images of gratings and pillars etched down to 300-400 nm depth using the PhSiAl hardmask. This calibre is remarkable because ~40 nm thick resist solely is able to work as an efficient hardmask for high-resolution lithography.
3.6 Miscellaneous Resists

There is a variety of commercial resists available with different lithographic parameters. For instance, incorporating metal into a material can boost the etch resistance of a resist. Metal salts of methacrylic acids (MAA), e.g. Pb, Ba, Ca and Sr, have been incorporated into PMMA resists. The sensitivity of PMMA was improved by a factor of 3 by the best-suited metal, i.e. Pb. Additionally, metal-impregnated PMMA resists better withstand acidic and basic etch chemistries compared to PMMA alone.

Along with the resist parameters, one major concern is the environmental and human impact of chemicals used in lithography processes. Keeping this point in mind, water-soluble resists have been reported for EBL technology that can help reduce the carbon footprint. In the next section, two different water-soluble resists are discussed.

With the purpose of achieving a creditable etch durability whilst lessening the environment impact, poly (sodium 4-styrenesulphonate) (PSS) was recently employed as an EBL resist. Sodium not only has a positive effect on the etch resistance but, due to the ionic nature of PSS, it can also be dissolved and developed in water. The resist solution was prepared by dissolving 70 kg/mol PPS (Sigma Aldrich) in DI water to make a 7 wt/vol% solution, which produced a thin resist film of approximately 180 nm. The film was then baked and exposed with a 20 keV beam to procure contrast curves and high-resolution patterns. Post exposure, the resist was developed with DI water for 10 s at room temperature. Figure 24 illustrates the contrast curve for the PSS resist along with its chemical structure and the high resolution patterning by EBL in PSS.

From the contrast curve in Figure 24(a), the sensitivity of 2800 µC/cm² is poor, as is the contrast of 0.8. However, the authors suggest that the use of higher molecular weight PSS to improve its sensitivity drastically, since for the cross-linking polymer chains the exposure dose is found to be inversely proportional to its molecular weight. However, the resist would not be ideal for high-resolution patterning as the EBL process would be extremely sluggish. For testing the etch resistance, an O2 plasma RIE test (20 sccm O2, 20 mTorr, 20 W RF power) of PSS was compared to PMMA. PSS
showed 17 times higher etch resistance than PMMA, and 6 times higher than SU-8 and polystyrene resists (from literature), which have similar sensitivity and contrast to that of PSS. Since PSS contains metal sodium, higher tolerance to dry etching is expected as compared to PMMA. The etch test with CF$_4$ gas (20 sccm CF$_4$, 20 mTorr, 100 W RF power, room temperature) revealed that the selectivity relative to PMMA was only 3.5 times higher. This low selectivity with CF$_4$ is thought to be because of the low percentage of sodium in PSS. Finally, to assess the resolution of this poorly sensitive resist, high-resolution gratings and pillars were exposed on a 180 nm thick resist film. The resist was not good for dense exposures and gratings with 100 nm spacing. The critical dimensions achieved were 60 nm linewidth with 400 nm pitch (Figure 24(b)) and pillars with a mean diameter of 60 nm with 300 nm pitch (Figure 20(c)), which is quite reasonable for a 180 nm thick resist film. However, gratings with lower spacing and pillars smaller than 40 nm in diameter collapsed due to the capillary force during drying after water development. Additionally, the authors demonstrated a metal lift-off of 2 keV exposed structures by DI water. To conclude, although PSS is not a model resist for fast and dense critical patterning, it definitely exhibits an excellent etch durability. Moreover, the fact that it can be developed and further processed with water makes it environmentally friendly and less hazardous for humans.

Engineers in Tufts University, US, have developed an apparent ‘green alternative’ resist.$^{74}$ Silk, a biologically fabricated material, has long been enjoyed as a luxurious and beautiful fabric, yet it is tougher than most of the synthetic fibres currently present in the market.$^{75}$ For this reason, silk proteins have been utilised in recent years in areas as diverse as photonics, electronics, drug delivery and bioscaffolds.$^{75-77}$ Recently, engineers in Tufts University expanded the possibility of using silk as a nanofabrication material. They showed that EBL was able to change the protein structure upon irradiation thus making it a candidate for EBL resists. This report demonstrated that the silk resist could be used as either a negative (amorphous silk form) or positive (crystalline silk form) resist. Moreover, silk can be converted into ‘functional resists’ by doping the resist solutions with organic, inorganic or even biologically active materials. In this segment, silk resist preparation, sensitivity values and resolution will be discussed.

Resist solutions were produced by boiling silk cocoons in sodium carbonate solution to obtain fibres, which were then dried overnight. The dried fibres were subsequently dissolved in 9 M lithium bromide resulting in a ~7 % aqueous resist solution of silk fibroin. The resist was then spun onto a substrate to give a 200 nm thick silk layer; the thickness of which could be controlled by the spin speed. In order to yield a negative resist, after spin coating the intermolecular crosslinking within the resist was achieved by either exposing the substrates to water vapour for > 12 h or by dipping in methanol for 60 s, followed by exposure to water vapour for 2 h. Both resists were typically exposed with high-energy beams of 100 and 125 keV. The development of the resists was done by simple immersion in DI water for 60 s followed by drying.

The minimum doses required to fabricate nanostructures at 100 keV were reported. In the case of the positive resist, the dose required to fabricate nanoscale features was 2250 µC/cm$^2$ and that for the negative form was 25,000 µC/cm$^2$. These values are 2.5 times higher than that required by PMMA at 100 keV.$^{78}$ Figure 21 illustrates photonic crystals having various spacing obtained by EBL exposure of both varieties of the silk resist.

Figure 25. (a-c) SEM images of photonic crystals fabricated with positive silk whereas (d-f) are with negative silk; with a lattice constant or periodicity for (a) and (d) of 700 nm; for (b) and (e) 600 nm; for (c) and (f) 500 nm; (g) and (h) are 200 nm diameter holes and pillars, respectively; (i) and (j) are highest resolution 30 nm holes and pillars patterned by the silk resist.$^{74}$

Evident from the SEM images shown in Figure 21 is that the ‘green’ resist is capable of fabricating nanostructures competently. Images from Figures 25(a-c) are the photonic crystals fabricated with a positive silk resist, whereas Figures 25(d-f) are produced with a negative silk resist, with lattice constant (periodicity) of 700 nm (Figures 25(a and d)), 600 nm (Figures 25(b and e)) and 500 nm (Figures 25(c and f)). The diameters of the crystals were designed to be 200 nm; and from the SEM images in Figures 25(g) and (h) it can be seen that there is no widening or narrowing of the structures, thus suggesting that the resist is capable of good lithography. Figures 25(i) and (j) illustrate the highest resolution obtainable with the two resists, that is, 30 nm holes and pillars with positive and
negative resists, respectively. Furthermore, the authors suggested that these resolution limits could be pushed further by tuning the molecular weight of the silk solution or by adding other biomolecules, for instance, microbial transglutaminase or mushroom tyrosinase. Thus, the possibility of using a biomaterial, silk, for EBL process was successfully demonstrated in this study. Moreover, another advantage of using silk, highlighted by them, is the ease of functionalising them to act like a unique class of bio-active resist. To conduct their tests, the silk solutions were doped with quantum dots, green fluorescent proteins (GFP) or horseradish peroxidase enzyme (HRP). They were able to validate the fabrication of high-quality nanoscale optics like quantum dots (inorganic) or GFPs (organic) that enhanced the fluorescent signalling from the silk devices. Dry etching was performed\textsuperscript{79} Etch rate with O\textsubscript{3} and C\textsubscript{4}F\textsubscript{6} gases constituted to be 9.10 nm/s. Although in its early stage of development, this is a new, eco-friendly resist which minimises the need to work with toxic chemicals and is potentially a step towards establishing a green cleanroom process.

4 ADVANCED LITHOGRAPHY

Top-down fabrication of the devices has, over the years, improved tremendously. Presently, the trend has diverted to three dimensional (3D) device fabrication.\textsuperscript{80} 3D devices find applications in a large number of fields including photonic crystals, biosensors and metamaterials.\textsuperscript{80,81,82} Especially the devices that are fabricated with the EBL technique require multiple steps and precise alignment of different layers.\textsuperscript{83,84,85} Besides the EBL method, advances in appliances employed in device fabrication are also being upgraded continuously and form the so-called next generation lithography (NGL) systems, which are briefly described earlier in section 1.2. Few of the charged particle NGL systems are discussed next.

Proton beam lithography or proton beam writing (PBW) is one of the techniques that are used for nanofabrication. Reports of utilising this technique for high aspect ratio and 3D fabrication are published, wherein multiple proton beams with different energies (and at different incident angles) are used for nanofabrication.\textsuperscript{86,87}

Helium ion beam lithography (HIBL) is also an example of a NGL process, which has successfully patterned not only non-traditional semiconductor materials but is capable of also directly patterning metals. It possesses a spot size down to 0.75 nm at an accelerating voltage of 30 kV, thus routinely enabling resolution down to 0.35 nm.\textsuperscript{88} Moreover, due to the fact that ions are much heavier than electrons, they experience less scattering in the resist and the substrate and the proximity effect experienced is almost negligible. They provide also faster resist exposure (higher sensitivity), potentially enabling resolution beyond that of EBL.\textsuperscript{89} Apart from being able to pattern resists down to 6 nm, helium ion beam also provides enhanced quality imaging as a microscope.\textsuperscript{89} A very recent study demonstrated that HIBL was able to pattern a fullerene derivative resist with sensitivity of almost three order magnitude more than EBL.\textsuperscript{90} Thus, due to the nature of ions, writing-times can be immensely reduced with this NGL technique.

EBL is well known for achieving critical resolutions with much ease but suffering from low throughput. In order to increase the throughput of this technique, multiple electron beam (multibeam) approach is currently under evaluation as an NGL tool.\textsuperscript{91} The two major applications of such systems are direct-write on wafer level and mask-making.\textsuperscript{92} There are various tactics that are considered for lithography like multiple columns, in which each beam source can have micro (for low voltage beams, 1-2 keV\textsuperscript{93}) or mini columns (1-50 keV beams\textsuperscript{94}). Other strategies are using a single column with multiple electron beam sources or distributed multiple beams where several beam sources are distributed over a portion or the entire area of the wafer.\textsuperscript{92}

The next generation lithography (NGL) techniques are, however, relatively expensive and not mature enough for widespread application. Their use for mass-production seems at the moment highly unlikely. Therefore, it is necessary to better understand these top-down techniques as well as to improve the existing techniques for nanoscale fabrication. Bottom-up techniques like directed self-assembly of block copolymers are also a promising technology favouring the progress of nanofabrication.

5 SUMMARY

Lithography is a vital element of nanoscale fabrication. In the last decade, the critical dimension of microelectronic devices has dramatically reduced while circuit complexity has increased.
Consequently, the requirement for microfabrication technology reaches into the nanometre regimen. In order to meet these requirements, the need has arisen for finer pattern generation and lithography systems with superior performance specifications. Advances in EBL systems have led to reduction in the beam size diameter down to 1-2 nm. However, achieving feature sizes equivalent to this small probe size remains difficult mainly due to the issues with resist morphologies and lithographic processes. To obtain the best outcome from any EBL process, the tool, the resist parameters and the overall lithography process must be optimised for good outcomes. All the resist parameters collectively described in Section 2 determine the quality of a resist. Nevertheless, it is not always that a single resist will exhibit all the parameters commendably, i.e. the resist may have a high resolution but may suffer low sensitivity value or etch durability. Due to the growing interest of lithography community to attain high performance lithography, there is a high motivation to develop novel EBL resists. This review summarises recent developments in EBL resists and compartmentalizes them into various families and expressing their various functions and merits. The resist families are classified according to their chemical compositions.

Firstly, the chemically amplified resists (CARS) were discussed and it is evident from the new, as well as, early reports that this division of resists are extremely sensitive to electron beam. State-of-the-art CARS exhibit electron sensitivity from 7 µC/cm² up to 200-300 µC/cm² and are able to offer high resolution structures down to 15 nm. The main issue with CARS is photo acid generation, not only during exposure but also in the interval between spinning the resist and exposure. This issue has been countered by casting a protective layer over the resist, which does not affect the sensitivity of the resist and protects it from unwanted alterations in the composition due to acid diffusion. Thus, by protecting the resists their stability is improved, which can lead to enhanced sensitivity and also ease patterning that requires mix-and-match lithography wherein one substrate requires two different patterning procedures with different or same tools. By controlling the acid diffusion within the resist after electron exposure and exploiting the advantage of high sensitivity of CARS, they project as worthy next-generation lithography resists. Conversely, in order to eradicate the additional unwanted acid-diffusion concerns of the CARS completely, non-CARS resists have been formulated. Such resists include mainly a sulphonium salt portion that will allow them to exhibit high sensitivity.

The infusion of a fullerene moiety, C₆₀, into various polymer blends leads to beneficial resist characteristics like high sensitivity and resolution, high etch resistance, low line width roughness and compatibility with industrial processing. Such materials can account for newer class of resists. In order to gain the best productivity from such resists, exploring more about their exposure mechanism, better understanding the role of C₆₀ in the whole EBL process and tuning resists parameters should be undertaken.

Methacrylate based resists are one of the generally favoured families of resists, due to the ease of handling and simplicity in their chemical formulation and exposure mechanism as compared to CARS or fullerene based resists. Conventional resists like PMMA, ZEP or SAL (Shipley Advanced Lithography) belong to this family of resists. Newer products from this family, such as SML or CSAR are favoured families of resists, due to the ease of formulation and exposure mechanism as compared to CARS or fullerene based resists. Conventional resists like PMMA, ZEP or SAL (Shipley Advanced Lithography) belong to this family of resists. Newer products from this family, such as SML or CSAR are modified to either have increased sensitivity, etch durability or high resolution.

The highest resolution of ~5 nm features has been achieved by EBL using inorganic resists. The widespread use of these resists is usually hindered due to their low sensitivity. HSQ is one of the most commercially and scientifically successful EBL resist, but it displays relatively low sensitivity. Therefore, inorganic resists have been recently prepared, which exhibit higher sensitivity while maintaining high resolution. Most of these new inorganic resists contain metal components such as hafnium, zirconium or aluminium. These resist do not only break the sensitivity limitations of inorganic resists but are also compatible for nanofabrication processes. They can be deposited easily from their aqueous solutions and also form even thickness films on substrates. A recent study reported use of colloidal nanocrystals, ZrO₂ and HfO₂ suspended in hexane, used as resists for plasma powered lithography. Wherein, hardmasks were pressed against the substrate but the exposure was caused by plasma power in etcher tool. This study supports the concept that the trend in inorganic resists seems to incline towards resists that are able to metallize after irradiation. Thus, eradicating process steps like metallization and lift-off.

Traditional EBL resists are mainly formulated with a view to gain maximum throughput over a fast processing period, often leading to the use of
hazardous chemicals for processing, or even the resists themselves can be perilous in nature. Recently, benign resist materials have also been developed like PSS, as described in miscellaneous resists section. Other resist that grasps this group are polyanilines water-based conducting EBL resists. Research towards non-hazardous and environment-friendly resists and developers may, in the future, become an important trend in developing new materials for nanofabrication.

In conclusion, in the past few decades, many materials have been suggested as potential EBL resists. High sensitivity and resolution together with good etch resistance continually remain the most desirable characteristics of EBL resists. The different classes of resists detailed in this report highlight the progress currently being made in the development of resist materials. With the EBL systems reaching their maturity in term of resolution, few NGL techniques are also reported in this paper. Table 5 summarises all the resists reported hitherto along with their family type, tones, developers, sensitivity and contrast values obtained at specific electron beam voltages and the critical dimension achieved by the resist. It is to be noted that in the cases where two or more resist derivatives were testified, only the ones with superlative performance are tabulated in table 5.

Table 5. Summary of the electron beam resists based on their family, tone; positive (P) or negative (N), developers, sensitivity, contrast, electron beam voltage, dry etch conditions, etch rates, critical dimension (CD) and the dense pattern features attained in the resists
