Abstract—We present an analysis of semiconductor optical amplifier (SOA) based differential Mach-Zehnder wavelength converters with a specific focus on optimizing performance through intentional asymmetries in optical power splitting, SOA bias, and interferometer phase bias. By introducing a simple conceptual framework for understanding the amplifier pulse dynamics, two simple yet effective design rules are derived. These design rules are validated using pseudo-random code in a comprehensive computer model, demonstrating the performance penalties that result when attempting optimization using only unequal SOA biasing or phase biasing. This work illustrates that dramatic improvements in extinction and eye margin can be achieved with optimized splitter asymmetries, and has significant implications for improved network performance and converter cascadability.

Index Terms—Optical Frequency Conversion, Optoelectronic devices, Optical Switches, Semiconductor Optical Amplifier

I. INTRODUCTION

All-optical wavelength conversion continues to attract considerable research interest for its potential to enable ultra-high-speed, low-cost, and efficient signal routing in wavelength-division-multiplexed networks. Semiconductor optical amplifiers (SOAs) have been key components in this research due to their large nonlinearities, enabling switching at conventional communications power levels, and to their potential for monolithic integration in highly compact and stable modules[1, 2].

Various configurations have demonstrated conversion speeds beyond limits suggested by carrier recombination times, including discrete trailing filter [3], delayed interference [4] arrangements, and differential Mach-Zehnder designs [5-9] incorporating embedded SOAs. It has been generally observed in the latter that improved switching performance is achieved through some means of asymmetrical operation including unequal drive currents to the SOAs, unequal optical injections, and unequal relative phase biasing of the interferometer. However, no simple analytical design rules have emerged for selecting asymmetries in high-speed wavelength converters to maximize performance, perhaps due to the assumed complexity of nonlinear SOA-pulse dynamics and the resulting need for intensive numerical modeling to capture realistic device behavior.

In this paper we introduce a simple conceptual framework to understand the impact of design asymmetries based upon our observation that major performance degradations result from (1) quasi-static imbalance of phase and power which impacts extinction ratio, combined with (2) dynamic phase imbalance that produces trailing satellite pulses. We develop first-order design rules for optimized asymmetries that minimize these two deleterious effects, respectively, for long strings of “0” data bits and isolated “1” data bits. We then validate the efficacy of these design rules under more realistic operating conditions by employing pseudo-random code in a comprehensive numerical model for SOA dynamics, illustrating that dramatic relative increases in eye margins are achieved for optimized asymmetries. We summarize our results in the conclusion, which is followed by an appendix describing the computer model and a brief derivation of results used in the text. This work clearly illustrates the hazards of assuming that high performance can be achieved through optimized asymmetrical electrical and phase biasing alone, and provides prescriptive tradeoffs between the phase and optical injection asymmetries that are generally required to achieve optimized performance.

II. WAVELENGTH CONVERTER OPERATION

A typical differential Mach-Zehnder interferometer (MZI) wavelength converter [6] is shown above in Fig. 1. An unmodulated probe beam (λ_{probe}) enters a power splitter (β_{probe}), propagates through the SOA pair, and for non-inverting operation combines destructively at the output. The π phase difference needed for destructive interference at the converter output can be realized through a static phase shift (φ₀), asymmetrical SOA optical and current injections, or some combination of both. Optical data pulses (λ_{signal}) divide at
\( \beta_{\text{signal}} \) and are injected into the SOAs. The data signal dynamically saturates the SOA and induces gain and phase deviations at \( \lambda_{\text{probe}} \) through nonlinear cross-phase modulation (XPM) and cross-gain modulation (XGM). An optical delay, \( \tau \), in the data signal path preceding SOA2 allows a data pulse to reach SOA1 first; XPM and XGM on the probe inside SOA1 disrupts the destructive interference at the MZI’s symmetric output coupler and creates the rising edge of a pulse. The same process then occurs in the SOA2 path a time \( \tau \) later, enabling SOA2 to rebalance the interferometer and re-establish the destructive interference for the falling edge of the output pulse at \( \lambda_{\text{probe}} \). This switching window defines the converted data pulsewidth and allows the MZI converter to operate at bit-rates well beyond what would be possible using only the SOA’s relatively slow phase recovery. In fact, though we have modeled a 40 Gb/s wavelength converter throughout this paper, we believe that the design rules we develop should work reasonably well in >100 Gb/s systems.

To accurately model SOA-based wavelength converter performance, we employ a comprehensive numerical modeling wave SOA model, outlined in Appendix A, that includes hot-carrier dynamics and rigorously calculates the phase response without invoking an \( \alpha \)-factor approximation [10]. As an example of the utility of our model, Fig. 2 illustrates the impact that a static phase shift has on the converter performance when symmetrical power splitters are used, i.e. \( \beta_{\text{probe}} = \beta_{\text{signal}} = 0.5 \). Figs. 3a and 3b depict the MZI output with a 40 Gb/s return-to-zero (RZ) input data signal consisting of 8 ps pulses in a 2^7-1 pseudo-random bit sequence (PRBS). At each value of \( \phi_0 \), the relative SOA injection currents have been reset to obtain the optimum output eye at \( \lambda_{\text{probe}} \), characterized by both the extinction \( X \), where

\[ X \equiv 10 \cdot \log_{10} \left( \frac{P_{\text{avg}}}{P_{\text{avg}}^0} \right) \]

and opening \( O \), where

\[ O \equiv \left( \frac{P_{\text{min}}^1 - P_{\text{max}}^0}{P_{\text{avg}}^1 - P_{\text{avg}}^0} \right) \]

The opening \( O \) captures the impact of pattern effects, whereas the extinction ratio \( X \) is sensitive to DC offsets to which \( O \) is relatively insensitive. The power levels used to calculate \( X \) and \( O \) are defined in Fig. 3b and the data input parameters are \( X_{\text{input}} = 42 \) dB and \( O_{\text{input}} = 0.99 \).

To generate the data in Figs. 2-3, the current into one of the SOAs is dropped until a total relative phase shift of \( -\pi \) is attained; the eye degradation is most dramatic when \( \phi_0 = 0 \) and the phase shift is achieved solely through asymmetrical SOA current injections. The poor extinction ratio is due to the impossibility of providing both equal output powers and a \( \pi \) phase shift on the probe output leading to incomplete destructive interference.

The use of a static phase shift allows the probe powers to balance and substantially improves both the eye extinction and opening, though significant degradation due to ringing and pattern effects remain, and would clearly lead to performance penalties even when received by a detector with bandwidth optimized for 40 Gb/s.

Origins of the poor eye performance are further elucidated in Fig. 4 which contains temporal plots of the two SOA phase responses. The probe phase shifts arise from signal-induced XPM, with the transmission window opening due to the saturation of SOA1 from the data pulse. When SOA2 is saturated to shut the transmission window, SOA1 has partially recovered and the different SOA phases and gains lead to imperfect destructive interference manifested through the emergence of trailing satellite pulses [11] and reduced extinction. Changes in SOA bias can only be used to trade-off between these two effects, leading to the relatively poor eyes in Fig. 3 which illustrate results with the best possible combination of SOA current injections.

The strong impact of \( \phi_0 \) on converters with symmetrical splitters suggests that either precise fabrication control of intentional phase delay, or some form of active phase control, is desirable. However, even at the optimum there is > 1.2 dB penalty in eye opening. This clearly illustrates that an MZI converter design incorporating symmetrical 3 dB power splitters produces a relatively poor output eye, even with a nominal \( \pi \) static phase shift inside the interferometer. The use of optical filters [3, 12-14] is likely to have contributed to the favorable performance of earlier reports of symmetrically designed MZI converters [5].

We will now show that power asymmetries in the probe and signal paths, rather than phase asymmetries, can be used to both maximize the DC extinction for an arbitrary \( \phi_0 \) as well as eliminate satellite pulses by enabling matched outputs in spite of SOA1’s partial recovery. Furthermore, the dependence of the output eye on the static phase shift is shown to be significantly reduced.

We do not explicitly evaluate polarization dependencies here, which effectively implies single polarization operation or polarization-independent modal gain. Polarization-dependent modal gain coupled with different polarization inputs in the system would result in polarization dependence in the ideal power splitter designs. If there were drifting input polarizations, this would lead to a performance penalty, but we show later in Figs 6b and 7c that this system is fairly robust against minor deviations from ideal operating conditions and splitter design values.

The following section describes a simplified conceptual picture of how the optimization of the MZI converter can be achieved through the design of the power splitters, and demonstrates through the numerical model the dramatic performance improvements that can result.

### III. Power Splitter Design

Based upon the observations above, the asymmetries in data
and probe splitters should be chosen such that (A) with no input data signal, the two probe SOA outputs are equal in amplitude and obtain a π relative phase offset from each other, and simultaneously (B) the phase and gain responses of the two SOAs properly align in amplitude during recovery to eliminate trailing satellite pulses [4, 15, 16].

To achieve condition (A), we can use static SOA device characteristics to determine the proper splitting of input probe power \( P_{\text{probe}} \). For a given output from one of the SOAs, for example, we would need to vary both the input power and the drive current to that SOA in such a way as to achieve an output that perfectly balances the output from the other for destructive interference. If we adjust the current to maintain constant SOA output power while the input optical power varies, it is shown in Appendix B that the phase deviation \( \delta \phi \) with SOA input power \( P_{in} \) will vary according to (1) below

\[
\frac{d \delta \phi}{d P_{in}} = -\frac{\alpha}{2} \frac{1}{P_{in}} \tag{1}
\]

Here \( \delta \phi \), \( P_{in} \), and \( \alpha \) are the probe SOA output phase, probe SOA input power, and linewidth enhancement factor, respectively. Integrating (1), we seek the pair of probe input powers that yields the π phase shift needed to meet optimization condition (A)

\[
\begin{align*}
\delta \phi_2 - \delta \phi_1 &= -\pi + \phi_0 = -\frac{\alpha}{2} \ln \frac{P_{in,2}}{P_{in,1}} \\
&\implies P_{in,2} = P_{in,1} e^{\frac{2}{\alpha} (\pi - \phi_0)}
\end{align*}
\tag{2}
\]

where \( 0 \leq \phi_0 \leq \pi \). Solving for \( P_{\text{probe}} \), yields

\[
\beta_{\text{probe}} \equiv \frac{P_{in,1}}{P_{in,1} + P_{in,2}} = \frac{1}{1 + \frac{P_{in,2}}{P_{in,1}}} = \frac{1}{1 + e^{\frac{2}{\alpha} (\pi - \phi_0)}}
\tag{3}
\]

where \( \beta_{\text{probe}} < 0.5 \) indicates a smaller optical injection into SOA1. The –π in (2) results from our choice that the nominal operation of SOA2 has a smaller current and higher optical injection. The space switch analysis in [17] is consistent with (3) under different design constraints, and (3) is applied here as a proposed optimization for the the high-speed MZI wavelength converter.

We attempt to achieve optimization condition (B) through the selection of \( \beta_{\text{signal}} \) to ensure the best scaling of phase and gain responses for proper temporal alignment during recovery. For this simple optimization argument, we ignore any differences in temporal gain and phase recovery behavior and focus on balancing the phase excursion which can be expected to impact satellite pulses to a greater degree. The impact of this simplification will be implicitly evaluated at 40 Gb/s through our numerical simulations which inherently include significant differences in gain and phase recovery. For example, some dissimilarity in the temporal behaviors of the gain and phase recoveries is expected simply due to the exponential behavior of gain for a given imaginary index excursion, but also from the detailed impact of ultrafast dynamical effects such as carrier-heating that are included in the numerical model [10].

If we denote the phase excursion of an SOA induced by a signal pulse as \( \Delta \phi \), then the two phase excursions should be equal at \( t = \tau \) (the optical delay preceding SOA2). The relative magnitudes of the phase excursions should then be governed by a ratio denoted as \( \eta \) which is given by

\[
\frac{\Delta \phi_2}{\Delta \phi_1} = e^{-\frac{\tau}{0.46 \sigma}} \equiv \eta
\tag{4}
\]

where the SOA recovery is modeled as a simple exponential for this qualitative discussion, and \( \sigma \) is the 10% to 90% exponential recovery time constant which is assumed equal for both SOAs.

\( G_{j,2} \) and \( \Delta \phi_{j,2} \) are the gain minima and phase deviations due to the signal pulse, respectively, and are shown in Fig 5. They relate through the \( \alpha \)-factor according to

\[
\Delta \phi = \frac{\alpha}{2} \cdot \ln \frac{G_1}{G_{01}}
\tag{5}
\]

where \( G_{01} \) is the steady-state gain preceding the signal pulse in SOA1. The ratio of phase changes is then

\[
\eta \equiv \frac{\Delta \phi_2}{\Delta \phi_1} = \frac{\alpha_2}{\alpha_1} \ln \frac{G_2 / G_{02}}{G_1 / G_{01}} \leq \ln \frac{G_2 / G_{02}}{G_1 / G_{01}} \tag{6}
\]

and \( \beta_{\text{signal}} \) must be chosen so that \( \eta \equiv \eta_0 \) or

\[
\eta = -\frac{\ln \left( \frac{G_2 / G_{02}}{G_1 / G_{01}} \right)}{\ln \left( \frac{G_1}{G_{01}} \right)} \equiv e^{-\frac{\tau}{0.46 \sigma}} = \eta_0
\tag{7}
\]

Memory effects will clearly lead to a variation in \( \eta \) across different bit sequences, but in this work we postulate that good optimization can be achieved by evaluating (7) following the injection of an isolated one-bit into the SOA pair. The SOA gain ratios contained in (7) are easily measured on a high-bandwidth oscilloscope, and this equation gives a clear picture of the rationale for the asymmetry. As stated earlier, the gain and phase recoveries are not identical, and the recovery rates
are not truly exponential as they generally depend on the SOA operating conditions. Despite these qualifications, we demonstrate in the next section that $\sigma$, and thus $\eta_{\text{fb}}$, are relatively constant across a large span of input powers and bias currents, allowing for good optimization with a fixed splitting ratio $\beta_{\text{signal}}$.

IV. NUMERICAL CONFIRMATION

The key results from the preceding section are (3) and (7), and their utility is now evaluated in a realistic operating scenario using a comprehensive SOA computer model. Appendix A contains a description of the model along with the SOA device parameters. The optical and electrical bias points must be selected so that the probe outputs are equal in power and together with the static phase shift, $\phi_0$, obtain a $\pi$ relative phase shift. To determine these operational points, a probe beam at 1547 nm is injected into the SOA and its output power is plotted logarithmically and normalized, (1) is rewritten

$$\delta\phi = -\alpha \ln(10) \left\{ 10 \cdot \log_{10} \frac{P_{\text{in}}}{0.001} \right\} + C_0$$

$$= -\frac{\alpha \ln(10)}{20\pi} P_{\text{in, dBm}} + C_0$$

(8)

where $C_0$ is an integration constant of no consequence.

A linear fit of $\delta\phi$ vs. $P_{\text{in, dBm}}$ indicates a slope of $\approx -0.17$, which corresponds to an $\alpha$ of 4.6. While the model does not use an $\alpha$-factor approximation in its calculations, the nearly constant slope of $\delta\phi$ in Fig. 6a indicates that for this static consideration the effective $\alpha$ behavior across the operational regime is constant, suggesting that a static $\beta_{\text{probe}}$ will work well across a wide range of input powers. The $\alpha$ of 4.6 is also quite typical for experimental values of bulk SOAs as modeled here. Using this value for $\alpha$ and setting $\phi_0$ to zero, (3) indicates $\beta_{\text{probe}} = 0.2$, i.e. a 20/80 power coupler should be utilized at the probe input along with appropriate bias currents. Fig. 6b contains the results from a more extensive sampling of the parameter space and illustrates the variation of the probe DC extinction with $\beta_{\text{probe}}$. The plot indicates a typical interferometer-like transfer function, and even a variation of as much as $\approx 25\%$ in $\beta_{\text{probe}}$ allows for an extinction of at least -30 dB.

Because $\alpha$ will have some probe wavelength dependence, the ideal $\beta_{\text{probe}}$ will vary according to the $\alpha$ variation as captured in (3). For a fixed $\beta_{\text{probe}}$, this wavelength variation can be accommodated to a limited extent through the adjustment of SOA bias currents, though this also unbalances the output powers. For large variations in probe wavelengths, a dynamically adjustable power splitter [18] or phase bias [16] could be advantageous in restoring the equalized output powers and $\pi$ phase offsets.

To achieve condition (B), $\beta_{\text{signal}}$ is chosen so that (7) is satisfied. A numerical experiment was executed to evaluate the left hand side of (7), and condition (A) is maintained by choosing $\beta_{\text{probe}} = 0.2$ while the SOA current biases are chosen to maximize DC extinction. The resultant SOA states are SOA2 @ (347 mA/8.8 dBm) (i.e. input current/input power) and SOA1 @ (360 mA/14.6 dBm) and the probe wavelength is still 1547 nm. An isolated 8 ps pump pulse at 1567 nm is injected into each SOA and the resultant peak gain excursions at 1547 nm were calculated. $\eta$ was thus modeled over a range of signal input powers and demonstrated good agreement when compared with the actual phase change ratios calculated in the model.

The phase recovery time ($\sigma$) of the 1547 nm probe must be known in order to evaluate the right side of (7). While this would be measured experimentally in a real device, Fig. 7a tabulates the results of a phase recovery fitting in our numerical model spanning a large range of data input pulse powers and SOA operating points. The variation of $\sigma$ is seen to be relatively small and a representational value of $\approx 28$ ps is chosen to evaluate (7) yielding $\eta_0 \approx 0.5$. With this value of $\eta_{\text{fb}}$, condition (B) dictates that $\beta_{\text{signal}}$ be adjusted so as to achieve $\eta \approx 0.5$ on the left side of (7). While it is not clear a priori that a fixed value of $\beta_{\text{signal}}$ can achieve this over a useful range of input powers, Fig. 7b illustrates the numerically evaluated variation of $\beta_{\text{signal}}$ required to achieve a given value of $\eta$ as a function of total signal input power. It can be seen that for $\eta=0.5$, a signal splitting of $\beta_{\text{signal}} = 0.5$ yields a good approximation to the desired phase excursion scaling over a broad range of input powers. Fig. 7b also clearly indicates that $\eta$ does vary with input power, which is expected given the asymmetrical optical and electrical injections. Variance can also be expected with input wavelengths leading to some violation of the criterion denoted in (7), but given a static $\beta_{\text{signal}}$, some accommodation to (7) could be realized by dynamically tracking the SOAs’ current biases and the total probe input power to the MZI.

The sensitivity of the choice of $\beta_{\text{signal}}$ is evaluated by varying the peak signal power into SOA2 and adjusting $I_2$ to optimize the output eye parameters $X$ and $O$. The results are shown in Fig. 7c which indicates a full-width half maximum (FWHM) for $X$ of $\approx 35\%$ of $\beta_{\text{signal}}$. Furthermore, our choice of $\beta_{\text{signal}}=0.5$ sits in a sweet spot between the maxima for $X$ and $O$.

The computer model is then used to evaluate the efficacy of the splitter asymmetries based upon the simple design rules above. The same numerical experiment carried out earlier to evaluate the output eye performance as a function of static phase shift is repeated for these asymmetrical MZI designs, but
now the two power splitters are optimized for each of the static phase shifts according to the design rules given by (3) and (7). Examples of the resulting operational parameters are summarized in Table I, which provides selected values of the design parameters for near-ideal eye performance at a given static phase shift. The probe and signal wavelengths remain \( \lambda_{\text{probe}} = 1547\text{nm} \) and \( \lambda_{\text{signal}} = 1567\text{nm} \) and the same 2\(^{\text{nd}}\)-1 PRBS word is used to evaluate the eye extinction \((X)\) and opening \((O)\) at the converted output.

When comparing the symmetrical (dotted) and the asymmetrically continuously optimized (solid) converter data curves, the largest performance enhancement occurs at \( \phi_0 = 0 \) with 21.5 and 4.6 dB improvements in the extinction and opening, respectively. The difference narrows as \( \phi_0 \) approaches \( \pi \), but significant improvements of 12 and 1.5 dB for \( X \) and \( O \) are still realized with the asymmetrical splitters.

The curve displaying the behavior of a converter with a fixed value of \( \beta_{\text{probe}} = 0.34 \), which was optimized for \( \phi_0 = \pi/2 \) (dash), also demonstrates a favorably decreased sensitivity of the eye opening to changes in the static phase shift, with even the most severe penalty in \( O \) being below 0.7dB over the entire range. Of course, at its optimum point it produces a very small penalty of \(< 0.3\text{dB} \) relative to unity. This curve, with fixed asymmetric \( \beta_{\text{probe}} \), also maintains at least 10dB extinction over the entire range of \( \phi_0 \).

These observations lead us to the major conclusions of this paper: (1) static optical phase shifts alone will not necessarily produce an optimized eye, and (2) converters with proper choice of splitter asymmetries provide outstanding performance without the need for perfectly optimized static phase shifts. In particular, a significant penalty in both \( X \) and \( O \) will be incurred if symmetrical power splitters are used, regardless of the phase shift utilized in the MZI, while a design with optimized splitter asymmetry will produce outstanding eyes at the design static phase shift but also very good eyes at other values of static phase shift.

### V. CONCLUSIONS

We have demonstrated the poor wavelength converter performance that can arise when utilizing 3-dB power splitters in a Mach-Zehnder configuration, and that these degradations are only partially mitigated through the use of static phase shifts. The utilization of a few simple and well-known SOA approximations has enabled us to derive two compact equations leading to the design of more appropriate asymmetrical power splitters for both the input probe and signal beams. A comprehensive computer model was used to validate these design principles with realistic pseudo-random code. We have also shown that proper choice of splitter asymmetries can result in dramatic improvements in eye quality with diminished dependence on static phase shift. The resulting eye quality, as illustrated for example by Fig. 9, clearly carries the potential for significant improvements in network performance and also converter cascadability.

We have not explicitly examined here the wavelength sensitivities of the power splitter designs, which we expect to manifest primarily through the wavelength dependence of both the dynamic amplitude phase coupling (usually captured through the \( \alpha \) factor) and the XPM phase shifts. We used our numerical model to estimate the changes in \( \alpha(\lambda) \) across the C-band, which were then inserted into (3) to calculate the variation in \( \beta_{\text{probe}} \). A comparison of this variation with the

results in Fig. 6b suggests that the optimized splitter design should provide fairly robust DC extinction with wavelength change. Gain changes with wavelength will also affect the choice of $\beta_{signal}$, though the results in Figs 7a-c also suggest resistance to the potential performance degradation from this effect. The incorporation of dynamical power splitters or phase bias could aid in the wavelength tunability of this system.

ACKNOWLEDGMENT

The authors wish to thank colleagues at Alcatel-Lucent Bell Laboratories, and Jesse Simsarian in particular, for helpful discussions and ideas that have contributed to this work.

APPENDIX A

COMPUTER MODEL

A computer model is used to characterize the SOAs’ behavior and validate the design principles proposed in the preceding treatment. A 40 Gb/s system is characterized through the implementation of a bulk-SOA traveling wave rate equation model including ultrafast effects due to carrier heating [10, 19]. The material gain is calculated using a density matrix approach which eliminates various linearizing approximations, e.g. the $\alpha$-factor. The isotropic complex refractive index calculated from the density matrix model is given by:

$$\tilde{n}(\omega) = \frac{\mu^2_{\omega}}{4\pi\epsilon_0 n} \left( \frac{2m_e}{\hbar^2} \right)^{\frac{3}{2}} \cdot \left( f_e + f_h - 1 \right) \sqrt{\frac{\hbar}{\Omega}} \cdot \int_{-\infty}^{\infty} \left[ -\frac{1}{2} T_2 + \frac{1}{2} \left( \omega - \frac{\epsilon_f}{\pi} - \Omega \right)^2 T_2^2 \right] d\Omega \right.$$  \hspace{1cm} (A1)

The imaginary part of (A1) corresponds to the material gain while the real part contains the contribution to the refractive index of the resonant band-to-band transitions. $T_2$ is the dephasing time, while $\omega$, $\mu_{\omega}$, $m_e$, $n$, and $E_g$ represent the optical angular frequency, dipole matrix element, reduced mass, background (non-resonant) refractive index, and bandgap energy respectively. $f_e$ and $f_h$ are the Fermi-Dirac occupational probabilities for electrons and holes. The rate equations are shown below.

$$\left( \frac{\partial}{\partial t} \pm v_g \frac{\partial}{\partial z} \right) S^\pm_{\omega} = \nu g \sum_{\omega} \left[ S_{\omega}^+ - \alpha_{PC} N - \alpha_0 \right]$$  \hspace{1cm} \text{and}  \hspace{1cm} (A2)

$$\left( \frac{\partial}{\partial t} + v_g \frac{\partial}{\partial z} \right) \delta \varphi_{\omega} = -\nu g \left( \frac{e}{c} \right) \cdot \left( \delta n_{b-h,\omega} + \delta n_{\text{plasma},\omega} \right)$$  \hspace{1cm} (A3)

$$\frac{dN}{dt} = \frac{I}{qV} - \nu_g \sum_{\omega} \left[ S_{\omega}^+ + S_{\omega}^- \right]$$  \hspace{1cm} (A4)

$$\frac{dT}{dt} = \frac{1}{\partial U/\partial T} \left( \frac{dU}{dt} - \frac{\partial U}{\partial N} \frac{dN}{dt} \right) - \frac{T - T_0}{\tau}$$  \hspace{1cm} (A5)

Equation (A2) describes the evolution of the forward and reverse propagating signals as well as the amplified spontaneous emission (ASE) photon density, $S$, where $v_g$, $\Gamma$, $g_{\omega}$, and $\alpha_0$ are the group velocity, waveguide confinement factor, frequency-dependent material gain, and passive waveguide loss, respectively. Free-carrier and inter-valence band (IVB) absorption are captured in $\alpha_{PC}$ and $R_{sp,\omega}$ is the spontaneous emission rate, described below.

$$R_{sp,\omega} = \frac{2 \Gamma^2 \cdot g \cdot \Delta \omega}{2\pi \cdot A_{act}} = \frac{2 \Gamma^2 \cdot n_{sp} \cdot g \cdot \Delta \omega}{2\pi \cdot A_{act}}$$  \hspace{1cm} (A6)

where $A_{act}$ and $\Delta \omega$ are the active region area and the spectral width of the ASE calculation, respectively. $g'$ and $g''$ are the stimulated emission and absorption components of the gain, calculated from (A1), where $g = g' - g''$ [20]. $n_{sp}$ is the commonly used spontaneous emission factor. ASE has been included to accurately capture the saturation dynamics, and so a high spectral resolution is unnecessary. $\Delta \omega$ is split into three wavelength regions centered on the ASE peak. ASE has been excluded from the output eye calculations.

The forward-propagating signal phase is described in (A3) with terms for the frequency-dependent refractive index changes due to the dipole band-to-band transition ($\delta n_{b-h}$) and the plasma ($\delta n_{\text{plasma}}$). $\delta n_{b-h}$ is calculated using (A1) and the Drude model is used to calculate $\delta n_{\text{plasma}}$ [21]

$$\delta n_{\text{plasma}} = \frac{-\lambda^2 q^2 N}{8\pi^2 \epsilon_0 n c^2 m_e}$$  \hspace{1cm} (A7)

where $\lambda$, $q$, $N$, $\epsilon_0$, and $c$ are the optical wavelength, electron/hole charge, carrier density, permittivity of free space, and the speed of light, respectively.

The carrier density changes are described in (A4) which contains terms for the electrical current, $I$, cavity volume, $V$, as well as the linear, bi-molecular, and Auger recombination coefficients denoted by $A$, $B$, and $C$, respectively.

Carrier heating is captured in (A5) using a carrier temperature rate equation, where $U$ is the carrier plasma
energy density. The plasma-phonon interaction is expressed in
the phenomenological addition to the r.h.s. of (A5) which
describes the restoration of the carrier temperature to that of
the lattice temperature, $T_0$, with the time constant $\tau$. The
temperature for electrons and holes, as well as their density,
are assumed to be equal at all times. The $dU/dt$ term is
evaluated using a simple expression for the rate of energy
change from stimulated emission as well as free carrier and
IVB absorption

$$\frac{dU}{dt} = -\sum_i (\hbar\omega_i - E_g) v_F g_{\alpha_i} (S_{m_i}^+ + S_{m_i}^-) + \sum_i \hbar \omega_i v_F \alpha_{FC} N (S_{m_i}^+ + S_{m_i}^-) .$$  \hspace{1cm} (A8)

The summation is used to include contributions from all
relevant optical frequencies.

The remaining derivatives on the r.h.s. of (A5) are evaluated
using the relationship between the energy density and the
carrier distributions

$$U = \frac{2}{\sqrt{\pi}} kT [N_e F_{3/2} + P_v F_{3/2}]$$  \hspace{1cm} (A9)

where $N_e$ and $P_v$ are the effective density of states
expressions for the conduction and valence bands, and $F_{3/2}$ is
the Fermi-Dirac integral of order 3/2 [22].

Our initial modeling with spectral hole burning suggested its
overall impact to be relatively inconsequential and it was
eliminated from further calculations. Typical parameters for
an InGaAsP SOA [20, 22] were used and are shown in Table
II.

These equations are solved on a space-time grid using the
method of characteristics in conjunction with a fourth order
Runge-Kutta solver implemented in Matlab. An injection
current of 350 mA produces a gain peak around ~ 1548 nm of
~ 32 dB. The 3 dB bandwidth for the gain stretches over ~
20nm and a 1547 nm signal quickly saturates the gain at an
input power of -23 dBm, indicating the ease with which this
SOA can be saturated and operated in the nonlinear regime.
All optical splitters and couplers are assumed loss-less and
wavelength-independent. The SOA output optical power ($P$)
is calculated from the photon density ($S$), and the MZI output
is calculated as

$$\frac{1}{2} \left| \sqrt{P_1} \cdot e^{i\delta \phi_1} + \sqrt{P_2} \cdot e^{i\delta \phi_2} \right|^2$$  \hspace{1cm} (A10)

where, for example, $P_i$ and $\delta \phi_i$ are the output power and
signal phase from SOA1.

APPENDIX B

In the absence of a data input signal, the probe output power
$P_{out}$ is static and is given by

$$P_{out} = e^{i\delta \phi_1} P_{in}$$  \hspace{1cm} (B1)

If $P_{in}$ varies but the current is maintained such that the
output $P_{out}$ is unchanged, then along such an operating curve
we must have

$$\frac{dP_{out}}{dP_{in}} = 0$$

$$= \frac{dP_{in}}{dP_{in}} \cdot e^{i\delta \phi_1} P_{in} \int_0^L dz g \frac{dg}{dP_{in}} dz \cdot e^{i\delta \phi_1} P_{in} \int_0^L dz g \frac{dg}{dP_{in}} dz$$  \hspace{1cm} (B2)

$$= e^{i\delta \phi_1} P_{in} \int_0^L \frac{dg}{dP_{in}} dz \left( 1 + P_{in} \int_0^L \frac{dg}{dP_{in}} dz \right)$$

and thus

$$-\frac{1}{P_{in}} = \int_0^L \frac{dg}{dP_{in}} dz$$  \hspace{1cm} (B3)

However, we can express the last integral in this expression as follows:
\[
\Gamma \int_0^L \frac{dg}{dP_{in}} dz = -\frac{1}{\alpha} \cdot \frac{\Gamma}{\lambda} \int_0^L \frac{4\pi}{\lambda} \frac{dn_{\text{real}}}{dP_{in}} dz
\]

\[
= \frac{2}{\alpha} \cdot \frac{d\delta \phi}{dP_{in}}
\]

and we have

\[
\frac{d\delta \phi}{dP_{in}} = -\frac{\alpha}{2} \frac{1}{P_{in}} \frac{\Delta n_{\text{real}}}{\Delta n_{\text{imag}}}
\]

where \( \frac{\alpha}{\Delta n_{\text{imag}}} \) is the usual \( \alpha \) factor.

Fig. 1. All-optical wavelength converter utilizing an active Mach-Zehnder interferometer. A longer optical path length preceding SOA2 provides the optical time delay, $\tau$. The phase shift ($\phi_0$) is considered a static design element.

Fig. 2. Eye extinction (X) and opening (O) vs. static phase shift, $\phi_0$. Dash-dot lines denote data taken by adjusting $I_1$ and using a $\phi_0 < 0$. Conversely, the solid lines describe the eye variation when $I_2$ is adjusted with $\phi_0 > 0$.

Fig. 3a. The best obtainable eye with $\phi_0 = 0$ when using symmetric power splitters and adjusting the current injection. No optical post-conversion filtering or detector electrical filtering is used and ASE noise is intentionally excluded from eye calculations. The eye diagrams display significant degradation from pattern effects even with optimized biasing.

Fig. 3b. The best obtainable eye with $\phi_0 = \pi$ when using symmetric power splitters and adjusting the current injection. The power levels used in calculating the two eye parameters, X and O, are also shown.

Fig. 4. Two SOA output phase responses are shown along with the output pulse intensity. The $-\pi$ phase shift between the two phase responses has been removed for clarity. Origins of trailing satellite pulses and poor zero-bit extinction can be seen.

Fig. 5. Phase recoveries for the two SOAs. $\Delta\phi_{1,2}$ is the magnitude of the phase shift for SOA1,2 and $\tau$ is the temporal shift due to the optical delay preceding SOA2.
Fig. 6a. The phase evolution of the probe output while maintaining a constant output power, calculated without invoking an α-factor approximation. The constant slope suggests a single choice for βprobe will work consistently across a broad input power range. This is a graphical depiction of the behavior predicted by the simple relation of (1).

Fig. 6b. The variation in DC extinction with βprobe. Current injection is optimized at each data point.

Fig. 7a. A plot of the probe (1547nm) phase recovery time (σ) vs the data signal (1567nm) pulse peak power. η₀ is calculated from σ using (4) and τ = 8ps. η₀ varies little across a large range of input pulse powers and SOA operating points. The input probe power is adjusted at each level of current injection to yield a constant probe output power.

Fig. 7b. βsignal plotted along lines of constant η as a function of total input power to the signal splitter. For example, if a total signal input power of -2 dBm is input to the MZI, and η₀ ≈ 0.5, the plot indicates a 50/50 power splitter should be utilized for the data signal.

Fig. 7c. The variation of the eye extinction (X) and opening (O) with the signal power splitter, βsignal. Current bias is optimized at each data point.

Fig. 8. The eye extinction (X) and opening (O) as a function of the static phase shift, φ₀. The dotted line depicts the data for symmetrical power splitters and is borrowed from Fig 2. The dash data shows the variation in eye performance for a converter optimized for operation at φ₀ = π/2. The solid line illustrates the best converter performance when both power splitters are asymmetrically optimized for each value of φ₀. Note that φ₀ ≥ 0 for the asymmetrical converters and φ₀ ≤ 0 for the symmetrical MZI. Current bias is optimized for each data point.
Fig. 9. Optimized asymmetrical MZI output eye with $\phi_0 = 0$.
