First principles static and dynamic calculations for the transition metal hydride series MH₄L₃ (M = Fe, Ru and Os; L = NH₃, PH₃ and PF₃)†

Nicolas Sieffert,a,b Thomas Kendrick,c Davide Tianad and Carole A. Morrison*c

We present a first principles static and dynamical study of the transition metal hydride series MH₄L₃ (M = Fe, Ru and Os; L = NH₃, PH₃ and PF₃), with a view to arriving at an understanding of how the variation in the electronic properties of the metal sites and ligands can influence the dynamics of the resulting complexes. A broad range of behaviour was observed, encompassing stable classical minima (M = Os, L = NH₃ and M = Ru, L = PH₃) to stable η²-H₂ non-classical minima (M = Fe, L = PF₃ and M = Ru, L = PH₃ or PF₃), with the other structures exhibiting dynamical behaviour that spontaneously converted between the classical and non-classical states during the molecular dynamics simulations. The importance of a small Lₐxₐₐ-M-Lₐxₐₐ angle in stabilising the non-classical state is highlighted, as is a short η²-H₂-Hₐₐ distance in non-classical complexes that spontaneously convert to the classical form. We also investigated the changes in the electronic structure of the complex FeH₄(PH₃)₃ during a η²-H₂ bond breaking/bond making reaction and observed direct evidence of the ‘cis effect’, whereby a neighbouring hydride ligand acts to stabilise the intermediate classical state.

Introduction

Transition metal (TM) hydrides are at the heart of many chemical reactions, such as hydrogenation,1 dehydrogenation,2,3 decarbonylation4 and hydrogen-transfer.1,5 Of these, dehydrogenation reactions have found particular interest in catalysis,6 for they create the potential to generate molecular dehydrogenation reactions have found particular interest in catalysis, decarbonylation and hydrogen-transfer.1,5 Of these, dehydrogenation reactions have found particular interest in catalysis,6 for they create the potential to generate molecular

occupied $t_{2g}$ orbital set to be utilised for the metal-H$_2$ forward-bonding interaction and a vacant d$_{xz}$ (e$_g$) orbital for the back-bonding interaction. $^{17}$ $^{3}$ Row transition metals are unlikely to support a dihydrogen ligand, as relativistic effects lead to an enhance core screening effect, thus rendering the valence d-orbitals more available to participate in backdonation, which in turn leads to cleavage of the dihydrogen bond. All ligands have a role to play, with those in the axial and equatorial positions either pushing or pulling electron density onto or from the metal, and thus altering the availability of the metal orbitals for bonding to H$_2$. From early density functional theory (DFT) studies, it is known that the length of the dihydrogen bond depends directly on the nature of the ligand trans to the H$_2$ unit, with σ-donor ligands such as hydrogen (as used in this study) generally resulting in very short H–H distances of around 0.9 Å. $^{10,11}$ This arises due to a trans labilizing effect, which reduces σ-donation from H$_2$ thus weakening M–H$_2$ binding, causing the H–H distance to contract. $^{18}$ Moreover, the barrier to H$_2$ rotation can be lowered by the presence of a hydride cis to H$_2$, in a phenomenon known as the ‘cis-effect’, whereby a two-electron interaction between the orbitals σ$_{M–H_2}$ and σ$^*$ H$_2$ results in a preferential conformation for the H$_2$ ligand that eclipses the M–H$_2$ bond. $^{19}$ This overrides the conformational setting dictated by the backdonation orbital interaction, which would otherwise position the H$_2$ ligand perpendicular to the equatorial plane. $^{20}$

Among the various examples of highly fluxional hydrides, the [MH$_4$(L)$_3$] (M = Fe, Ru and Os; L = phosphines) family has gained particular attention in the literature. For instance, a rotation motion has been reported in the case of the OsH$_4$L$_3$ (L = PM$_2$Ph) complex, $^{19}$ possibly accompanied by a significant deformation of the OsL$_4$ fragment within the transition structure. $^{8}$ The n$^2$H$_2$ ↔ 2H scrambling motion has also been investigated and is shown to involve the breaking of the dihydrogen bond to afford a transient classical tetrahydride. The whole process is expected to occur with the four hydrogen atoms remaining in the equatorial plane. Relatively small activation barriers (in the range of ca. 8 kcal mol$^{-1}$) have been determined experimentally. $^{5}$

In the most part, where data have been obtained from computational studies, the structures reported are those of the most stable geometries, as obtained from “static” optimizations. A more realistic picture can be gained by explicitly considering the dynamics of the complexes, i.e. considering their intrinsic vibrational motions and permitting the effects of temperature to be included. We recently applied density functional theory molecular dynamics (DFT-MD) simulations to study the dynamical behaviour of a series of [MH$_4$(PH$_3$)$_3$] complexes (M = Fe, Ru and Os), focusing on the description of the anharmonic vibrational features encountered in these complexes. However, we also showed in this study that a dynamical exchange between classical and non-classical isomers can be directly observed within the course of a simulation (in a 30 ps timescale). $^{21}$ Others have since also reported the direct observation of a classical/non-classical transition for transition metal hydride complexes. $^{15}$ Recently, hydride migration around low-coordinate metal centres containing N-heterocyclic carbenes has also been investigated by DFT-MD simulations. $^{22}$

Herein, we build on our first study, $^{21}$ to further investigate the dynamical mechanisms involved in TM hydrides by means of DFT-MD simulations. Our approach involves the screening of several metals and companion ligands and aims to arrive at an understanding of how the variation in their electronic properties can influence the dynamics of the resulting complexes. In selected cases, clear dynamical equilibria corresponding to the rotation and scrambling pathways [as presented in Scheme 1] can be observed during simulations (i.e. many events occur within 30 ps), a feature that therefore allows us to provide statistical pictures of the behaviour of the complexes by plotting correlation diagrams between selected geometrical parameters. Correlations between geometrical and electronic parameters (namely energies of molecular orbitals) are also presented. All data taken together allow us to better understand how the bonding system evolves under the effect of an elevated temperature (350 K, i.e. in a case where hydrogen tunnelling should be negligible; vide infra).

As target systems, we chose a series of complexes conforming to the formula [MH$_4$L$_3$] where the metal M is Fe, Ru, or Os.
and the ligands are L = NH₃, PH₃, and PF₃, such that different combinations of M and L permit the “fine-tuning” of the electronic structure of the complexes. All metals can be considered to be in a low-spin d⁶ configuration and in a pseudo-octahedral environment, thus presenting full occupation of the t₂g orbitals to support M–H₂ back-bonding. The availability of those orbitals increases when going from Fe to Os due to increased core screening brought on by relativistic effects. For the ligands, NH₃ was selected as a small ligand that acts as a pure σ-electron donating ligand (from the nitrogen lone pair). This ligand should therefore increase the ability of the metal centres to back-donate, which should result in a less stable dihydrogen bond. Conversely, PH₃ and PF₃ are generally considered to be simultaneously σ-donating (from the phosphorous lone pair) and π-accepting ligands (into the P–H/F σ* orbital). Overall, these ligands can therefore withdraw more electron density from the metal centres, and thus should lessen the ability of the metal to backdonate into the H₂ σ* orbital, resulting in a more stable η²-H₂ unit.

For all complexes, static optimizations have first been performed in order to characterise the nature of the stationary points (minima or transition states) of the different isomers (A–C, Scheme 1) and to get insights into the relative kinetic barriers and driving forces of the rotation and scrambling pathways. Next, we performed extensive DFT-MD simulations to gather statistical information on the geometric parameters involved in making and breaking the dihydrogen bonds in these complexes. Analysis of the time evolution of the electronic structure for the complex FeH₄(PH₃)₃ has also been performed, posteriori, using snapshots extracted from the DFT-MD simulation.

### Computational methods

#### Static calculations

Reaction energies presented in Table 1 were computed from static optimisations obtained using Gaussian09. The geometries of all the complexes have been optimized using the PBE functional in conjunction with small-core Stuttgart/Dresden “SDD” pseudopotentials (describ-
ing 10, 28 and 60 core electrons for Fe, Ru and Os, respectively) and their associated basis sets on the metals (Fe, Ru and Os) and the 6-31G** basis set on all other elements. Then, improved energies were calculated at the PBE/SDD/6-311+G** level (i.e. improving the basis set description on all elements except for the metal atoms) by performing single point calculations on the PBE/SDD/6-31G** structures. Corrections to obtain free energies were computed at the PBE/SDD/6-31G** level from harmonic frequencies without scaling, at 350 K and a pressure of 1 atm. Transition states were characterised by a single imaginary frequency, describing either the H₂ rotation or the η²-H₂ ↔ 2H scrambling mechanism. Because some energies differences are small and sometimes at the limit of the accuracy of DFT, we performed single point calculations, on selected complexes, at the high CCSD(T) level in conjunction with the same SDD ECPs on M and larger aug-cc-pVTZ basis sets on all other elements. Molecular orbitals beyond a cut-off value of −10 a.u. were frozen, i.e. corresponding to the three inner molecular orbitals in the cases of [MH₄(NH₃)₃] and [MH₄(PH₃)₃] complexes, and the twelve inner molecular orbitals in [FeH₄(PF₃)₃]. The analysis of the molecular orbital coefficients shows that the frozen orbitals essentially correspond to the 1s atomic orbitals of N, P and F. These calculations were performed with NWChem 6.1.1.26

**Molecular dynamics (DFT-MD).** The same DFT-MD protocol as in our previous study has been employed.²¹ Born-Oppenheimer MD simulations were performed using the Quickstep²⁷ scheme as implemented in the CP2K package,²⁸ in which the Kohn–Sham orbitals are represented by atomic basis sets and the electron density is represented in a plane waves basis. The MOLOPT basis sets were employed at a mixture of double-zeta (for the metal) and triple-zeta (for all other elements) levels. A 300 Ry cutoff was employed for the expansion of plane waves, in conjunction with Goedecker-Teter-Hutter pseudopotentials,³⁰ which provided an energy converged per atom of 3 meV. The exchange/correlation functional PBE was used throughout.²⁴ Atomic coordinate models for each TM hydride complex were placed in a periodic cubic cell 15 Å long, effectively modelling an isolated-molecule system. Following geometry optimisation, molecular dynamics simulations were run for 32 ps in the NVT ensemble, choosing a target temperature of 350 K (via a chain of Nose–Hoover thermostats³¹,³² with a time constant of 4 a.u.) in order to minimise the impact of quantum nuclear effects. For every time step of 0.55 fs, the electronic structure was explicitly quenched to a tolerance of 10⁻⁶ Hartree. We checked that these parameters do not induce any bias in the dynamics of the hydride ligands by performing an additional MD simulation of [FeH₄(NH₃)₃] using a halved timestep (0.275 fs) and a tighter convergence criterion for the wavefunction (10⁻⁷ h), that showed an almost identical behaviour and probability distribution between the classical and non-classical forms (compare Fig. 1 and S1†). For all simulations, the first 2 ps of MD have been discarded to allow for equilibration time in the analysis of the trajectories. Trajectories involving [MH₄(PH₃)₃] complexes (with M = Fe, Ru and Os) were taken from our previous study.²¹

**Importance of quantum mechanical tunnelling**

Quantum mechanical effects on the dynamical behaviour of TM hydrides are well recognized but are known to occur only at rather low temperature (i.e. up to 150–200 K).³³ An estimate of the importance of tunnelling can be obtained from the
crossover temperature $T_c$ (in K), defined as follows:

$$T_c = \frac{\hbar \nu}{2\pi k_B}$$

where $\hbar$ is the Planck constant, $\nu$ is the absolute value of the imaginary frequency corresponding to the transition mode (in Hz) and $k_B$ is the Boltzmann constant. $T_c$ marks the temperature (in K) where tunnelling and thermally activated barrier crossing are roughly equally important (as an example, $T_c$ is about room temperature when $\nu = 1300$ cm$^{-1}$). Imaginary frequencies for all transition states are provided in ESI† (Table S1). The latter range from 491 cm$^{-1}$ (rotation pathway in [OsH$_4$(NH$_3$)$_3$]) to 520 cm$^{-1}$ (scrambling pathway in [OsH$_4$(PF$_3$)$_3$]) and therefore correspond to $T_c$ generally below 100 K (namely, ranging from 11 K to 119 K), i.e. well below the temperature considered herein ($T = 350$ K). The corresponding Wigner correction factors are generally small (between 1.00 and 1.10, and somewhat larger in the case of [OsH$_4$(PF$_3$)$_3$] where it amounts to 1.19; see Table S1†). When two transition states were located for a given complex (for rotation and scrambling paths), we note that $T_c$ and Wigner correction factors are very similar, in such a way that the relative rate of rotation vs. scrambling is little affected by the quantum correction (see rate constants in Table S1†). Herein, we therefore considered that quantum mechanical tunnelling does not influence the conclusions of our study and this effect was not accounted for (neither in our static calculations based on classical transition state theory nor in our DFT-MD simulations where nuclei are described as classical particles).

**Time evolution of molecular orbitals and electron charge density during $\eta^2$-$\text{H}_2 \leftrightarrow 2\text{H}$ scrambling reaction.** For the complex FeH$_4$(PH$_3$)$_3$, atomic orbitals have been computed using NWChem (version 6.1) by performing sequences of single points calculations at the PBE/SDD/6-31G** level on snapshots extracted from the MD trajectories. Snapshots have been taken every 5.5 fs (i.e. every 10 time-steps) in such a way that ca. 5400 single points have been analysed per system.

Finally, the H–H bond breaking event in FeH$_4$(PH$_3$)$_3$ has been analysed with the quantum theory of atoms in molecules (QTAIM) using the Promolden code. The electronic structures were calculated using a standard 6-31G* basis set for p-block elements and the phosphine hydrogen atoms, coupled to the PBE level of theory; a second polarisation function was added to this basis set description for a higher accuracy treatment of the hydrogen atoms attached to the metal centre. Hay-Wadt small core potential with its relative basis set was employed to describe Fe, and the metal core shell was reconstructed a posteriori. Snapshots from the MD trajectory have been extracted and used to calculate the charges and the delocalisation indices (DI) $\delta$.

Performing a topological analysis of the electron charge density $\rho$, allows the space to be partitioned into atomic basins, $\Omega$, which defines the atoms within the QTAIM approach. Integrating $\rho$ over $\Omega$ therefore provides the atomic charge $q_{\Lambda}$, since:

$$q_{\Lambda} = Z_{\Lambda} - \int \rho(r)dr$$

where $Z_{\Lambda}$ is the atomic number. The number of electrons shared between atomic basins $\Omega_a$ and $\Omega_b$ (or in other words the number of shared electrons between atom $\Lambda$ and $\Omega$) is given by the delocalisation indices $\delta_{\Lambda\Omega}$, in accordance with the following expression, where $\rho_{\text{ex}} = \text{exchange} - \text{correlation density}$.

$$\delta_{\Lambda\Omega} = -2 \int \int \rho_{\text{ex}}(r_1, r_2)$$

It should be noted that DFT calculations do not provide a proper 2nd order density matrix, and for that reason the values reported for $\delta$ are approximate only. However, it has been found that $\delta_{\text{DFT}}$ values are reasonable, and tend to be in good agreement with pure wavefunction values.

**Results and discussion**

**Static calculations**

We first discuss the results from the static geometry optimisations of the MH$_4$L$_4$ complexes ($M = \text{Fe, Ru and Os}; \text{L} = \text{NH}_3$, $\text{PH}_3$ and $\text{PF}_3$), as presented in Table 1. Definitions of all of the stationary point structures obtained on the potential energy landscapes can be found in Scheme 2, and a table listing more selected geometric parameters is given in the ESI† (see Table S2), along with Cartesian coordinates of selected optimised geometries.

The relative energies (and the thermodynamically-corrected free energies) of the optimised structures obtained on the potential energy surfaces show the trends we expected from varying $M$ and $L$, with the trends observed in the DFT calculations mirrored in the CCSD(T) calculations (see Table 1). When $M = \text{Fe}$ the non-classical state (with the $\eta^2$-H$_2$ ligand sitting parallel to the equatorial plane) is always preferred to the classical, and as the electron withdrawing properties of the 2-H$_2$ ligand and very short H–H bond lengths (0.99, 0.90 and 0.88 Å for $L = \text{NH}_3$, $\text{PH}_3$, or $\text{PF}_3$, respectively) this suggests that electron withdrawing properties of the auxiliary ligands have all but ‘switched off’ the $\pi$-backdonating auxiliary orbital exchange, resulting in a more freely rotating $\eta^2$-H$_2$ ligand and very short H–H bond lengths (0.99, 0.90 and 0.88 Å for $L = \text{NH}_3$, $\text{PH}_3$ and $\text{PF}_3$, respectively, see Table S2†). Interestingly, the $\text{L}_{\text{axial}}$–$\text{Fe}$–$\text{L}_{\text{axial}}$ angle ($\alpha$) also becomes more bent as the ligand becomes more electron withdrawing [171.9° ($L = \text{NH}_3$), 156.8° ($L = \text{PH}_3$) and 146.8° ($L = \text{PF}_3$)], and...
with the barrier to the \( \eta^2-\text{H}_2 \) ligand sitting perpendicular to the equatorial plane dropping, we see an increase in the \( \eta^2-\text{H}_2 \cdots \text{H}_2\cdots \text{H}_2\cdots \text{H}_2 \) distance, from 1.76 Å (for \( L = \text{NH}_3 \)) to 1.89 Å (for \( L = \text{PH}_3 \)) to 1.86 and 2.14 Å for the near iso-electronic \( L = \text{PF}_3 \) and perpendicular minimas, respectively. Thus as the ability of Fe to π-back donate electrons into the \( \sigma^* \) \( \text{H}_2 \) orbital is reduced the population of the classical structure becomes increasingly unfavourable.

The geometry optimisation calculations for the \( M = \text{Fe} \) series therefore suggest in total three different pathways, which are summarised pictorially in Scheme 2. When \( L = \text{NH}_3 \) the complex should be able to switch between the classical and non-classical states via the TS-scrambling pathway (route ‘a’ in Scheme 2), while the rotational pathway (where there are two routes – ‘b’ and ‘c’) are blocked. Switching \( L \) for \( \text{PH}_3 \) suppresses the TS-scrambling pathway, while opening up the rotational pathway, which proceeds via a transition state where the \( \eta^2-\text{H}_2 \) ligand is perpendicular to the equatorial plane (route ‘b’ in Scheme 2). Finally switching \( L \) for \( \text{PF}_3 \) further suppresses the TS-scrambling pathway and renders the perpendicular \( \eta^2-\text{H}_2 \) ligand geometry a minimum on the potential energy surface (route ‘c’ in Scheme 2).

Switching \( M \) to Ru now stabilises the classical form, provided \( L = \text{NH}_3 \). According to the molecular orbital diagram drawn in Scheme 1, with relativistic effects rendering the t\(_{2g}\) orbital set more available for bonding to \( \text{H}_2 \), an electron donating ligand will encourage π-back donation to σ* \( \text{H}_2 \) and thus sever the H-H bond, such that the classical state is the only one observed. This suggests that route ‘a’ in Scheme 2 should now be suppressed. The \( \eta^2-\text{H}_2 \) ligand lies parallel to the equatorial plane, with the barrier to \( \text{H}_2 \) rotation lying at least 5 kcal mol\(^{-1}\) above the minimum energy structure, also shutting down routes ‘b’ and ‘c’ for this system. These results therefore suggest that complex \( M = \text{Ru} \), \( L = \text{NH}_3 \) is effectively trapped in one well on the potential energy surface, corresponding to the classical structure. As the electron withdrawing properties of \( L \) increase the non-classical structure once again becomes the more stable state; for \( L = \text{PH}_3 \) the rotational and scrambling pathways are both accessed via transition state structures that are similar in energy, suggesting routes ‘a’ and ‘b’ are now open, while for \( L = \text{PF}_3 \) the barrier to the rotational pathway is significantly lower, suggesting route ‘b’ as the lowest energy pathway. Turning now to geometrical considerations, as \( L \) becomes more electron withdrawing angle \( \alpha \) reduces, with the Fe series, however a clear cut pattern in the \( \eta^2-\text{H}_2 \cdots \text{H}_2\cdots \text{H}_2\cdots \text{H}_2 \) distances is now less obvious. The classical minimum for the \( L = \text{NH}_3 \) complex results in a very short value for bond distance \( \eta^2-\text{H}_2 \cdots \text{H}_2\cdots \text{H}_2\cdots \text{H}_2 \) (1.66 Å), while the non-classical structures return much longer values, at 2.10 and 2.09 Å, for \( L = \text{PH}_3 \) and \( \text{PF}_3 \), respectively.

Finally when \( M = \text{Os} \), and \( L = \text{NH}_3 \) we again see a preference for the classical state. With the absence of a minimum for the non-classical state and a predicted high barrier to \( \eta^2-\text{H}_2 \) rotation, this complex should be trapped in one well on the potential energy surface, as with the Ru analogue. A similar story exists when \( L = \text{PH}_3 \), but now a stationary point for the “in plane” (\( \phi = 0^\circ \)) non-classical form could be located, and only an extremely low barrier (\( \text{ca. } \Delta E_{\text{calc}} = 0.1 \) kcal mol\(^{-1}\) at the PBE level) prevents its optimization towards the most stable classical structure. We note that the non-classical \( [\text{OsH}_4(\text{PH}_3)_2] \) complex exhibits the longest H1–H2 distance (1.02 Å) of the \( \text{MH}_4L_4 \) series (see Table S2†), and its structure is found to be very close to the TS-scrambling transition state (consistent with the very similar energies values obtained for the two structures in Table 1). Note the barrier to the rotational pathway is high, shutting down routes ‘b’ and ‘c’. When \( L = \text{PF}_3 \), the non-classical state is again a minimum, only slightly less stable than the classical global minimum (\( \text{<2 kcal mol}^{-1} \), see Table 1), with the scrambling and rotational pathways accessed via barriers of similar height (\( \text{<3 kcal mol}^{-1} \), see Table 1). Geometry considerations again indicate that angle \( \alpha \) decreases with increasing electron withdrawing capability of \( L \); no clear pattern emerges for the bond distance \( \eta^2-\text{H}_2 \cdots \text{H}_2\cdots \text{H}_2\cdots \text{H}_2 \).

**Molecular dynamics**

For characterisation of the spontaneous molecular motions observed during the production run trajectories, the following geometrical descriptors have been considered: (i) the difference in distances between \( d(\text{H}_1\cdots \text{H}_2) \) and \( d(\text{H}_1\cdots \text{H}_3\cdots \text{H}_4) \) (labelled \( \Delta d \), in Å), (ii) the dihedral angle involving \( \text{H}_1\cdots \text{H}_2\cdots \text{H}_3\cdots \text{H}_4 \) (\( \phi \),...
in degrees), (iii) the $\alpha_{\text{axial}}-\text{M}$-$\alpha_{\text{axial}}$ ($\alpha$, in degrees), and the $\eta^2$-$\text{H}_{2} \cdots$-$\text{H}_{3}$ distance [i.e. $d(\text{H}_{2}\cdots\text{H}_{3})$] (See Scheme 1 for atom numbering). Correlation plots between these parameters are depicted in Fig. 1–3.

It is immediately obvious from Fig. 1 and 2 that the dynamical behaviour of the series of complexes depends strongly on the choice of the metals and the ligands. If a complex accesses the scrambling pathway (route ‘a’, Scheme 2), where it

---

### Fig. 2 Correlation frequency maps between the angle $\alpha$ and $d(\text{H}_{1}\cdots\text{H}_{2}) - d(\text{H}_{3}\cdots\text{H}_{4})$ ($\Delta d$) for complexes $\text{MH}_{4}(\text{L})_{3}$.

### Fig. 3 Correlation between the non-classical/classical hydride exchange and the $\text{H}_{2} \cdots \text{H}_{3}$ ($d_{23}$) distance. Frequency maps for complexes of series 1 and 2 (see Scheme 1). Note for complexes [FeH$_4$(PH$_3$)$_3$] and [OsH$_4$(PF$_3$)$_3$], which show dynamic $\eta^2$-$\text{H}_{2} \rightarrow$ 2H behaviour, the identities of atom pairs ($\text{H}_{1}, \text{H}_{2}$) and ($\text{H}_{3}, \text{H}_{4}$) switch during the simulation, so some of the data presented in these plots relates to the longer distance $d(\text{H}_{1}\cdots\text{H}_{4})$.

interconverts between the classical and non-classical states, large variations in $\Delta d$ are expected; if it accesses the rotational pathway (route ‘b’, Scheme 2) large variations in $\phi$ are expected. Starting with $[\text{FeH}_4(\text{NH}_3)_3]$, the geometry optimisation calculations suggested that route ‘a’ only was to be expected. This is borne out in the MD results, where many exchanges between classical and non-classical forms occur within the 30 ps MD trajectory. Note the conformations with the largest population occur when $\Delta d \approx \pm 1.5 \text{ Å}$. Classical hydrides are also significantly populated (for which $\Delta d$ is close to zero) and a continuous motion from one form to the other is observed. The $\phi$ dihedral angle always remains close to $0^\circ$, clear evidence that the scrambling pathway is the one invoked for the $\eta^3\text{-H}_2 \leftrightarrow 2\text{H}$ exchange reaction. The $\eta^3\text{-H}_2$ ligand sitting parallel to the equatorial is accompanied by an $\alpha$ angle which remains close to linear throughout the simulation ($170 \pm 10^\circ$, Fig. 2, cf. 171.9° for the geometry optimised structure). The correlation plots for parameter $\eta^3\text{-H}_2 \cdots \text{H}_{cis}$ indicate a rather short average distance, of around 1.8 Å (Fig. 3) for the non-classical state. We note that the correlation plots are very symmetric, indicating that good sampling of the configurations of the system has been obtained.

When we switch to the less electron-donating ligand PH$_3$ we observe a dramatic change in behaviour. The geometry optimisation calculations suggested that the barrier to the rotational pathway should be significantly lower than for the scrambling pathway, and this is supported by the MD results. The non-classical $[\text{FeH}_4(\text{H}1\text{-H}2)\text{(PH}_3)_3]$ complex ($\Delta d = -1.0 \text{ Å}$ and $\phi = 0^\circ$) is overwhelmingly favoured. Rotation of the H$_2$ moiety occurs spontaneously in the course of the dynamics, as indicated in the spread of values for $\phi$ from $0^\circ$ to $\pm 180^\circ$ (Fig. 1), however the more populated regions correspond to $\phi = 0$ and $\pm 180^\circ$, indicating that the four hydride atoms lie flat in the equatorial plane for the majority of the time. Both $\Delta d = \pm 1.0 \text{ Å}$ regions are populated, but as the scrambling pathway was accessed only once during the dynamical trajectory, their probabilities are asymmetric. The static calculations suggested a higher activation barrier for the scrambling process (the classical structure was a transition state), which is borne out by the MD data. We note that $d(H_1 \cdots H_2)$ elongates noticeably when the ligand lies in the equatorial plane, possibly due to a $\eta^3\text{-H}_2 \cdots \text{H}_{cis}$ interaction. Angle $\alpha$ fluctuates around $155 \pm 15^\circ$ (see Fig. 2), similar to the geometry optimised value 156.8°, and again we see a population basin around 1.8 Å for $\eta^3\text{-H}_2 \cdots \text{H}_{cis}$ (Fig. 3).

When $L = \text{PF}_3$, the geometry optimisation calculations predicted that the rotational pathway would be favoured over the scrambling pathway, and this is indeed observed in the MD simulation, with the Fe complex remaining in its non-classical state during the whole 30 ps of MD. The probability distribution plot shown in Fig. 1 suggesting an almost freely rotating $\eta^3\text{-H}_2$ ligand, commensurate with the drop in barrier height predicted by the optimisation calculations, and $d(H_1 \cdots H_2)$ elongating slightly when the ligand lies in the equatorial plane. Angle $\alpha$ has dropped further, to around $145 \pm 15^\circ$ (see Fig. 2, cf. optimised structure 146.8°), while the population basis around 1.8 Å for $\eta^3\text{-H}_2 \cdots \text{H}_{cis}$ is reduced (Fig. 3), which presumably can be directly linked to the absence of an $\eta^3\text{-H}_2 \leftrightarrow 2\text{H}$ exchange reaction for this complex.

Switching the metal from Fe to Ru and Os, we again see that changing the auxiliary ligands NH$_1 \rightarrow$ PH$_3 \rightarrow$ PF$_3$ induces a shift from the scrambling pathway to the rotational one, with the switch occurring later in the case of Os (Fig. 1). This switch in pathway we attribute to the reduction in $\pi$-back donation between the metal t$_{2g}$ orbital and the ligand $\sigma^*$; the later switchover for Os can presumably be tied into the premise that relativistic effects will render the metal t$_{2g}$ orbital more closely involved in the frontier orbital set, and thus more strongly electron withdrawing ligands are required to induce the switchover. This change in pathway is also observed in the $\alpha$ angles (Fig. 2), with a close to linear configuration observed when the scrambling pathway is accessed, and an increasingly bent configuration supporting an increasingly more freely rotating $\eta^3\text{-H}_2$ ligand. The parameter density maps reveal interesting differences compared to the Fe analogues (Fig. 1). Whereas the non-classical forms are more populated for $[\text{FeH}_4(\text{NH}_3)_3]$, for $[\text{RuH}_4(\text{NH}_3)_3]$ and $[\text{OsH}_4(\text{NH}_3)_3]$ it is now the classical states that are preferred. The geometry optimisation calculations predicted these structures were essentially trapped in a single well, with a steeper exit barrier for the Os system, a result mirrored in the MD probability plots. For $[\text{OsH}_4(\text{PF}_3)_3]$, both the scrambling and rotational pathways are accessed, with the $\alpha$ angle widening for the classical state, commensurate with the near identical barriers for both routes predicted from the geometry optimisation calculations (Table 1). Concerning the $\eta^3\text{-H}_2 \cdots \text{H}_{cis}$ probability plots, for those structures that support an $\eta^3\text{-H}_2$ structure and no $\eta^3\text{-H}_2 \leftrightarrow 2\text{H}$ scrambling (i.e. $[\text{RuH}_4(\text{PH}_3)_3]$ and $[\text{RuH}_4(\text{PF}_3)_3]$) we observe that $d(H_2 \cdots H_3) > 2.0$ Å. For $[\text{OsH}_4(\text{PF}_3)_3]$, which does support scrambling the data is less clear cut, as the rapid fluxional $\eta^3\text{-H}_2 \leftrightarrow 2\text{H}$ behaviour means this plot is a combination of $d(H_2 \cdots H_3)$ and $d(H_1 \cdots H_4)$ data which affects the statistics of the data binning process, however it is apparent that a significant population of $d(H_2 \cdots H_3)$ ca. 2.0 Å is present.

Thus, to summarise, the results obtained from the MD trajectories and static geometry optimisation calculations point towards various key structural parameters that dictate whether the resulting complex adopts a classical, non-classical, or a dynamic $\eta^3\text{-H}_2 \leftrightarrow 2\text{H}$ structure. To support a non-classical hydride, it is clear that the angle $\alpha$ must be quite small, in agreement with the findings by Mitoraj et al. on molybdocene trihydride complexes. This can be achieved by the presence of auxiliary ligands that are strongly electron withdrawing, which interferes with the ability for the metal centre to $\pi$-back donate to the H$_2$ ligand, resulting in a freely rotating $\eta^3\text{-H}_2$ unit with a short H-H bond distance. Conversely, if the axillary ligands are electron donating, $\pi$-back donation is favoured; angle $\alpha$ widens and the classical state is favoured. To encourage dynamic $\eta^3\text{-H}_2 \leftrightarrow 2\text{H}$ behaviour the barrier height to the TS-scrambling state must be minimised, and the evidence points towards fluxional complexes having a short $\eta^3\text{-H}_2 \cdots \text{H}_{cis}$ distance in the non-classical state.
Time evolution of molecular orbitals, geometric parameters and topological analysis during $\eta^2$-$\text{H}_2 \leftrightarrow 2\text{H}$ scrambling reaction

We can use the MD trajectories to build up a representation of the changes in the properties and energies of the molecular orbitals (MOs) involved in the dihydrogen bond making/breaking process. This is done by sampling single-point energy calculations for geometries obtained from snapshots taken from the MD trajectories, and then plotting the resulting orbital energies and isosurfaces as the chemical reaction proceeds, or performing a more in-depth topological analysis such as QTAIM.

We have performed this analysis for [FeH$_4$(PH$_3$)$_3$], which undergoes just one $\eta^2$-$\text{H}_2 \leftrightarrow 2\text{H}$ scrambling reaction during the 30 ps MD trajectory. In Fig. 4 we present a timeline for the energies of the molecular orbitals in FeH$_4$(PH$_3$)$_3$ (from HOMO$^{-}_{-17}$ to LUMO$^+_{32}$) over a 180 fs period, with $t = 0$ marking the point at which $\Delta d = 0$ (i.e. the classical structure) is obtained. From Fig. 1 and 2 we observe that this complex exhibits nearly-free $\eta^2$-$\text{H}_2$ rotation and that $\Delta d$ is minimised when angle $\alpha$ widens, which coincides with the $\eta^2$-$\text{H}_2$ ligand rotating into the equatorial plane. Thus on Fig. 4 we denote that the $\text{H}_2$ ligand is first oriented perpendicular to the equatorial plane and at $t = -42$ fs it has rotated to adopt a parallel orientation. By $t = 90$ fs the non-classical hydride, with the $\eta^2$-$\text{H}_2$ parallel to the equatorial plane, is observed.

While large oscillations in the energies of the MOs are observed (ca. 0.02 Hartrees), which are due to the effects of temperature in the simulation, some orbitals are clearly seen to undergo significant change in energy (ca. 0.05 Hartrees) as the reaction proceeds. These are HOMO$^{-}_{14}$, HOMO$^{-}_{7}$, HOMO$^{-}_{4}$, HOMO$^{-}_{3}$, HOMO$^{-}_{2}$ and LUMO$^+_{13}$. The identities of these orbitals have been manually assigned through careful inspection of isosurface plots. We thus assign HOMO$^{-}_{14}$ to the $\sigma$-donation Fe(d$_{z^2}$)-$\text{H}_2(\sigma)$ bonding orbital, HOMO$^{-}_{4}$ and HOMO$^{-}_{3}$ are orbitals which involve the H$_{cis}$ and H$_{trans}$ ligands and the Fe metal centre, while HOMO$^{-}_{2}$ represents the $\pi$-back-donation Fe(d$_{xy}$/d$_{yz}$, depending on whether the $\text{H}_2$ unit sits perpendicular or parallel to the equatorial plane)-$\text{H}_2(\sigma^*)$ bonding orbital. HOMO$^{-}_{7}$ is a complex mix involving the p-orbitals from the phosphorous atoms, the Fe d-orbitals and a component from the $\text{H}_2(\sigma)$ bonding orbital; LUMO$^+_{13}$ is the antibonding partner to HOMO$^{-}_{2}$. All of these orbitals are

Fig. 4 Time evolution of the eigenvalues (in Hartree) of the molecular orbitals in [FeH$_4$(PH$_3$)$_3$] during the scrambling process. “perp.” and “paral.” denote a perpendicular ($\phi = 90^\circ$) and parallel ($\phi = 0^\circ$) orientation of the $\text{H}_2$ ligand with respect to the equatorial plane. Since HOMO$^{-}_{3}$ and HOMO$^{-}_{4}$ cross during the rotation of $\text{H}_2$ (at $t = -55$ fs), we labelled the molecular orbitals according to their order from $t > 55$ fs.
stabilized in the classical form \((t = 0 \text{ fs})\), with the exceptions of HOMO−14 and HOMO−7; these orbitals are both bonding with respect to the \(\eta^2\)-H2 ligand, which is destroyed when the classical structure is formed. The same information from Fig. 4 is portrayed as a scatter plot with reference to the parameter classical/non-classical switch parameter \(\Delta d\) in Fig. S2,† along with images of the orbitals mentioned, and how they evolve as the complex undergoes the \(\eta^2\)-H2 ↔ 2H scrambling reaction. The orbital timeline plots therefore appear to support the well documented ‘cis-effect’,20 whereby orbitals on a neighbouring hydride ligand act to stabilise the classical state.

From the orbital timeline plots in Fig. 4, we observe that the onset in change in energies occur ca. 50 fs prior to the \(t = 0\) crossover point. This also marks the point where geometrical changes occur in the \(\text{H} \cdots \text{H}\) distances, as shown in Fig. 5(a). Here we observe an oscillating \(\eta^3\)-H2⋯H3 distance (H2⋯H3), which shortens to around 1.75 Å, while the old \(\eta^1\)-H2 distance (H1⋯H2) begins to lengthen and the new \(\eta^2\)-H2 distance (H3⋯H4) begins to shorten. The topological analysis, performed on the same MD frames allows us to observe that the atomic charges on the \(\eta^1\)-H2 atoms [H1 and H2 in Fig. 5(b)] build up around the same time, indicating that charge is flowing into the old \(\eta^1\)-H2 ligand from the metal site, which echoes results obtained by Mitoraj for molybdocene trihydride complexes.15 Charge begins to drain from the hydride ligands (H3, H4) from around \(t = -40\) fs. The delocalisation indices for the Fe–H bonds [Fig. 5(c)] allow us to rationalise the change in relative strengths of these bonds during the scrambling process: the results indicate that around \(t = -50\) fs the Fe–H-(1,2) bonds strengthen quite dramatically; the Fe–H(3,4) bonds weaken, but only marginally during this time. Finally, we discuss the delocalisation indices for the \(\text{H} \cdots \text{H}\) bonds themselves, which are observed to be of equal strength at the \(t = 0\) classical structure [Fig. 5(d)]. By \(-50\) fs the old \(\eta^2\)-H2 distance (H1⋯H2) weakens rapidly, matching the trace from the atomic charges plot [Fig. 5(b)], while a spike on the new \(\eta^2\)-H2 distance (H3⋯H4) trace is observed at \(-30\) fs, matching a contraction to 1.5 Å observed on the geometry plot [Fig. 5(a)]. From the H2⋯H3 trace on Fig. 5(d) we again observe some direct evidence of the ‘cis effect’, with the delocalisation index rising for this neighbouring interaction as the H1⋯H2 distance begins to weaken. Once the classical structure has been reached, the new \(\eta^2\)-H2 distance (H3⋯H4) forms rapidly (<30 fs), as evidenced by all data shown in Fig. 5.

**Conclusions**

In this study we have performed a series of static optimisation calculations and molecular dynamic simulations on the family...
of compounds $[\text{MH}_4\text{L}_3]$, where $\text{M} = \text{Fe, Ru and Os}$, and $\text{L} = \text{NH}_3, \text{PH}_3$ and $\text{PF}_3$, with a view to arriving at an understanding of how the variation in the electronic properties of the metal and ligands influence the dynamics of the resulting complexes. The results point towards various key structural parameters that dictate whether the resulting compound adopts a classical, non-classical or a dynamic $\eta^2\text{-H}_2 \leftrightarrow \text{2H}$ structure. To support a non-classical hydride it is clear that the angle $\alpha$ must be quite small, in agreement with the findings of Mitoraj et al.\textsuperscript{15} This can be achieved by the presence of auxiliary ligands that are strongly electron withdrawing, which interferes with the ability for the metal centre to $\pi$-back donate to the $\text{H}_2$ ligand, resulting in a freely rotating $\eta^2\text{-H}_2$ unit with a short $\text{H} - \text{H}$ bond distance. Conversely, if the axillary ligands are electron donating, $\pi$-back donation is favoured; angle $\alpha$ widens and the classical state is favoured. To encourage dynamic $\eta^2\text{-H}_2 \leftrightarrow \text{2H}$ behaviour the barrier height to the TS-scrambling state must be minimised, and the evidence points towards fluxional complexes having a short mean $\eta^2\text{-H}_2 \cdots \text{H}_{\text{ad}}$ distance in the non-classical state. Of the set of nine compounds investigated, four were found to have $\eta^2\text{-H}_2 \leftrightarrow \text{2H}$ dynamical behaviour: $[\text{FeH}_4(\text{NH}_3)_3]$, $[\text{FeH}_4(\text{PH}_3)_3]$, $[\text{RuH}_4(\text{NH}_3)_3]$ and $[\text{OsH}_4(\text{PF}_3)_3]$. 

To investigate the changes in electronic structure during the dynamic scrambling reaction, geometric snapshots were taken from the MD trajectory for $[\text{FeH}_4(\text{PH}_3)_3]$, to plot the change in eigenvalues for the frontier orbital set, as well as to undertake a full topological analysis during the spontaneous $\eta^2\text{-H}_2 \rightarrow \text{2H}$ reaction. From this direct evidence of the well-documented ‘cis effect’ emerged, as orbitals involving the neighbouring hydride were stabilised and the $\eta^2\text{-H}_2 \cdots \text{H}_{\text{ad}}$ distance gained in strength in the timeline leading up to the appearance of the transition state classical structure.
