Many Facets of Photonic Crystals: From Optics and Sensors to Energy Storage and Photocatalysis

Alex Lonergan and Colm O'Dwyer*

The ability to selectively redirect specific wavelengths of light has attracted a lot attention for photonic crystal materials. Presently, there is a wealth of research relating to the fabrication and application of photonic crystal materials. There are a number of structures that fall into the category of a photonic crystal; 1D, 2D, and 3D ordered structures can qualify as a photonic crystal, provided there exists ordered repeating lattices of dielectric material with a sufficient refractive index contrast. The optical responses of these structures, namely the associated photonic bandgap or stopband, are of particular interest for any application involving light. The sensitivity of the photonic bandgap to changes in lattice size or refractive index composition creates the possibility for accurate optical sensors. Optical phenomena involving reduced group velocity at wavelengths on the edge of the photonic bandgap are commonly exploited for photocatalytic applications. The inherent reflectivity of the photonic bandgap has created applications in optical waveguides or as solar cell reflector layers. There are countless examples of research attempting to exploit these facets of photonic crystal behavior for improved material design. Here, the role of photonic crystals is reviewed across a wide variety of disciplines; cataloging the ways in which these structures have enhanced specific applications. Particular emphasis is placed on providing an understanding of the specific function of the tunable optical response in photonic crystals in relation to their application.

1. Introduction: Nanostructure, Biomimetics, and Structural Coloration

Nanostructures are widely used in materials research to optimize the performance or functional characteristics associated with a particular material in a system. Nanostructures used in microelectronics led to the development of nanoelectronics with more components per chip, improved performances, lower costs, and power consumption.^[1] Many other fields of research have also exploited the structural properties of nanomaterials for enhanced material performances in areas such as photocatalysis,^[2] energy storage,^[3] and biomedicine.^[4] A common advantage of nanomaterial structures is often the increased specific surface of the material compared to bulk counterparts, creating favorable geometries or increased surface reactions in many systems.^[2,5,6] Precise control over nanostructure feature sizes and geometries allows certain material responses to surface plasmon, electrical and optical prop-

erties to be governed to some extent by the existence of the nanoscale order. $^{\left[7-9\right] }$

The optical properties of a structure are particularly susceptible to variation based on the particular ordering involved in the composition of the nanostructure. The symmetry, spacing, and type of repeating structure are all important considerations for the optical appearance of the material. Nature provides many different and vivid examples of nanostructured materials and the interesting optical phenomena associated with structural order. Structural color is present throughout the natural world, where the colors associated with bird feathers, butterfly wings, and beetle shells arise from nanostructured materials as opposed to varying material compositions or dyes.^[10-12] Studying the lattices and finer structure of these materials provides an insight into the appearance and striking coloration associated with naturally occurring nanostructured materials which can exist as 1-, 2-, or 3D repeating structures.^[13] The variation in structural color, even between similar species, can be understood from the different types of nanostructured order present in the material.^[14] Iridescence observations, where certain viewpoints or angles appear to influence a material's color appearance, can also be explained for materials featuring structural coloration through consideration of

the light interaction and diffraction effects in these ordered materials. $^{\left[15,16\right] }$

In addition to structural color, certain naturally occurring phenomena can be understood by direct observation of the nanostructure associated with the material. One prominent example is the lotus effect.^[17] The specific spacing of the material nanostructure heavily influences the wettability of many types of plant leaves^[18] and other biological structures.^[19,20] In the case of lotus leaves, a strong structural hydrophobicity is achieved through the nanostructure of the leaf in combination with the hydrophobic properties of the waxes on the surface of the leaf.^[21] Figure 1 displays several examples of prominent nanostructured materials present in the natural world. The hydrophobicity of the lotus leaf is shown from the high water contact angle of a droplet sitting atop a lotus leaf surface in Figure 1b. Structural coloration is demonstrated via the vibrant colors and iridescence effects shown for butterfly wings, peacock feathers, beetle shells, sea mouse spines, opal gemstones, and begonia plant leaves. Microscopy examples of the fine structure of materials are displayed alongside images showing natural structural order. Figure 1 showcases just a sampling of the many instances of structural color occurring in the natural world.

Material designs or applications with inspirations from naturally occurring phenomena or structures can be classified

as biomimetic systems. The field of biomimetics is concerned with understanding and emulating systems found in nature for the purposes of establishing biologically inspired designs, adaptions or derivations.^[33] There are many examples of practical applications of natural biological structures. Biomimetic inspirations can be found in biological engineering.^[34] photonics.^[35] surface science,^[36] medical tissue engineering.^[37] and functional material designs.^[38] Through a combination of surface morphology, nano/microstructural design and the chemical composition of materials, many different effects can be imitated from biological constructs. Controlled hydrophilicity, surface adhesion, mechanical strength, anti-reflection, thermal insulation, aerodynamic lift and fluid drag reduction are among some of the biomimetic properties of commercial interest.^[33]

For a specific mechanical structural application of biomimicry, nacre layers composed of calcium carbonate and nanostructurally integrated biomolecules (proteins and polysaccharides) create ceramic materials with high mechanical strength in bivalves such as molluscs^[34,39] and are inspiring designs for biomedical implants due to their strong integration with bone tissue and excellent mechanical properties.^[40] Many emerging super hydrophobic or self-cleaning material surfaces feature structural design morphologies with prominent biomimicry of the lotus leaf effect.^[24,41,42] The fine nanostructure patterns found in moth eyes, a series of patterns and subwavelength bumps on the outer corneal lens, inspired the biomimetic development of anti-reflective coatings used to reduce reflections in surfaces such as those for solar cells.^[43–45] **Figure 2** demonstrates the close relation between the natural structure of materials and the biomimetic nanostructured materials they have inspired for some of the effects discussed here. Many more examples of biomimetic designs exist in the literature with nanostructure designs in the natural world providing a blueprint for imitation and application of specific effects in emerging technologies.

ADVANCED SCIENCE NEWS _____

The concept of ordered structures and associated optical properties, such as structural color, are found in materials classified as photonic crystals (PhCs). From the first suggestions of alternating dielectric slabs and their applications to light manipulation,^[53,54] PhCs have been explored for their inherent optical abilities. The periodic structural order present in PhCs acts to attenuate specific photon frequencies from propagating through the structure. This control over photon frequencies is known as the photonic bandgap or photonic stopband of the structure. Depending on the degree of frequency depletion, complete photon inhibition is most commonly described by a complete or omnidirectional photonic bandgap^[55] whereas partial or incomplete photon depletions are described by pseudo-photonic bandgaps or photonic stopbands.^[56,57] The photonic bandgap is often presented as an optical analog to the electronic bandgap associated with allowed electron energy levels in semiconductor materials.^[58] The placement of atoms or molecules in semiconductor materials forms a crystal lattice with a periodic potential which dictates the energy of electrons allowed to propagate through the semiconductor. Gaps in the energy band structure of the crystal lattice create forbidden electron energies in the material. For PhCs, the system of a periodic potential of atoms or molecules is replaced by a periodic dielectric function where different dielectric contrasts of larger ordered structures create similar effects for photons as seen with electrons. Much like in the case of semiconductor materials with band structures used to predict the electronic bandgaps of materials, the photonic bandgap can be predicted for materials through solutions of Maxwell's equations with specific knowledge of the lattice structure.^[58,59]

In addition to those occurring naturally, artificially structured PhCs are often manufactured and explored in relation to their ability to modulate certain frequency ranges of light. Artificial PhCs are architected in a variety of different structural forms depending on the application. In terms of the repeating nanostructure lattice, it is possible to form 1D (e.g. stacked dielectric slabs^[60]), 2D (e.g., arrays of dielectric rods with an ordered arrangement or patterned dielectric slabs with air perforations^[61,62]) and 3D PhC structures. Fully 3D PhCs can be designed as dielectric spheres in an air background (often called opals based on the arrangement of silica particles in an opal gemstone^[63]), inverse opal^[64] (IO) air spheres in a high dielectric background, a dielectric slab with holes drilled through at specific angles called a Yablonovite structure^[65] or layered stacks of dielectric rods forming a woodpile structure.^[66] Some of these common PhC constructs and designs are seen depicted in Figure 3. All structures display a periodic dielectric contrast in their composition, an essential component for establishing the photonic bandgap property of the material. Similarities between some of the natural nanostructure designs seen in Figure 1 can be seen for many of the artificially designed PhC structures.

Light interactions with specific and ordered PhC planes can be predicted based on light diffraction, using the Bragg-Snell model to project diffracted wavelengths from the photonic stopbands of structures. Using this model as a basis, maximum wavelengths of reflection from the structure are predicted for the maximum constructive interference condition in the reflected wave. The Bragg-Snell treatment combines Bragg's law of diffraction for x-ray diffraction in crystal lattices with Snell's law of refraction for light incident on media with different refractive indices. Depending on the spatial dimensions of the PhC, there are slight differences in the approach to estimate the wavelength of maximum diffraction. For a 1D PhC with alternating slabs of thicknesses d_1 and d_2 with corresponding refractive indices n_1 and n_2 and a resonance order of *m*, the central wavelength of maximum diffraction λ can be found from^[72,73]:

$$m\lambda = 2(d_1n_1 + d_2n_2) \tag{1}$$

The diffraction relation for 2D PhCs treated as diffractions gratings with a distance d_s between scattering centers and an incidence angle θ is often^[74,75] given as:

$$m\lambda = 2d_s \sin\theta \tag{2}$$

For 2D PhCs consisting of a monolayer of spheres, such as single-layer artificial opal templates, a variation of Equation 2 is sometimes applied to estimate λ , the central diffraction wavelength.^[76] For a groove spacing *d*, an incident angle α , a diffraction angle β , a free constant χ used in data fitting to account for spherical grooves, the following relation is applied to describe 2D sphere monolayer PhCs:

$$m\lambda = d\left[\sin\left(\alpha\right) + \sin\left(\beta + \chi\right)\right] \tag{3}$$

Many works featuring 2D PhCs tend to use band structure simulations to estimate the photonic bandgap or stopband. The appearance and properties of the photonic bandgap or stopband in 2D PhCs, such as those shown in Figure 3b,c, is governed by the refractive index contrast, grating distance periodicity and the ratio between the thickness of the scattering centers to the periodicity.^[61,77,78] A clearer picture of the signature photonic response is usually provided by band structure simulations compared to the simpler relation shown in Equation 2.

The Bragg-Snell law used for 3D PhC structures with alternating dielectrics of refractive indices n_1 and n_2 , a light incidence angle on the entire structure of θ_1 , an interplanar spacing of *d*, a resonance order of *m* and the central wavelength of maximum diffraction λ can be stated as follows:

$$m\lambda = 2d\sqrt{n_{\rm eff}^2 - n_1^2 \sin^2 \theta_1} \tag{4}$$

A more detailed explanation of the origins of certain parameters and the derivation of this equation can be found in Appendix I. Looking at the Bragg-Snell equation, the maximum wavelength

of diffraction is dependent on many factors associated with the structural composition of the PhC. The interplanar spacing (*d*), factors in the periodicity of the material and the overall geometry of the crystalline structure. The refractive indices ($n_1 \& n_2$) incorporate the optical properties of the alternating dielectric materials and control the magnitude of n_{eff} , the effective refractive index. By this relation, changes to any of these parameters should result in changes to the wavelength of maximum diffraction from the PhC structure. This is important for both interpreting and understanding the optical properties of the nanostructured materials and also design and development of an optical application using PhCs. Control over the size or constituent materials of the structure enables the optical response of the material to be tuned over specific wavelength ranges,^[79–81] if desired.

The tuning of the optical response of the material is an important consideration in the development of many artificial PhC structures for use in high sensitivity systems such as PhC display screens^[82,83] or sensors.^[84,85] Knowledge of the relation between nanostructure and optical behavior has furthered the understanding of many natural observations such as material iridescence or color changes associated with liquid infiltration.^[20,86] **Figure 4** displays some of the changes observed to structural coloration for both natural and artificial PhCs which can be understood through changes to the wavelength of maximum diffraction of the Bragg-Snell relation.

In terms of the optical response of these materials, understanding and predicting the light interaction process is critical when developing applications centered around the structural

color of the material. Advancements in the construction of colloidal particle templates have allowed for greater order and flexibility in the design of PhCs based on colloidal particle templating, such as opals and IOs.^[90,91] Feature sizes, defects, and material choice all act to influence the signature optical response of these materials. Tuning the optical response of prepared PhCs post-production has also been studied extensively, showing that factors such as stretching deformation^[92] or solvent infiltration^[93] among many others have important considerations for the structural color of the material.

Knowledge of the flexibility of the photonic stopband and the associated structural color of the material creates specialized applications involving the wavelength of light reflected from the structure. Electrical tuning of an opal template with infiltration of a metallopolymer substance has been demonstrated to tune the wavelength reflected from the structure and create a tunable photonic response, with potential applications in PhC color displays^[94] for substances dubbed photonic inks.^[95] This wavelength shift is attributed to the expansion and contraction of layer spaces in the material due to the swelling of the infiltrated material with an applied voltage. The magnetic response of the photonic bandgap of superparamagnetic colloidal nanoparticles has been exploited to develop anti-counterfeit PhC labels where the structural color of the anti-counterfeit strip is dependent on the applied magnetic field.^[96,97] Figure 5 illustrates the electrical

and magnetic tuning effects of the structure utilized in these applications. In these examples, the application of the PhC is directly linked to the structural color and the visual appearance of the material emphasizing the importance of understanding the effect of the photonic stopband and the factors which affect wavelengths reflected from the film surface.

Research into applications involving the structural color of PhC films is continually innovating with new advancements steadily emerging from the literature. The concept of tuning the light reflected from the film surface creates a fascinating application where the structural color detected visually can selectively be altered for an observer. Figure 6 details some of the recent studies which utilize the structural color effect of PhC films in their primary application. The work shown in Figure 6a is a prime example of biomimicry where the dermal layers of a gecko inspired the design for a temperature-dependent PhC film with tunable color and transmittance intensity by incorporating thermochromic and electrochromic pigments into the film. The environmental temperature was found to affect the color of the film and an applied voltage affected the transmittance of the film to light, with a suggested application to smart windows with a variable degree transmittance linked to an applied voltage.^[98] Controllable PhC film iridescence, where the structural color appears to vary with the viewing angle, has been explored for images printed with colloidal photonic

inks, as depicted in Figure 6b. For SiO₂ particles dispersed in acrylate-based resins, the relative degree of viscosity of the dispersion resin was found to impact the vibrancy and iridescence of structural color for the printed images with broader reflection peaks and less iridescent images found to arise from higher viscosity resins.^[99]

Automotive paint coatings based on SiO₂ photonic crystals in a solvent medium spray coated onto surfaces and re-coated with a commercial clear coat are shown in Figure 6c. The resultant PhC films displayed vibrant colors which could be tuned by the SiO₂ particle size or by using combinations of different sizes to achieve films of mixed colors. Films were resistant to mechanical and chemical stress tests and exhibited high structural color iridescence making them attractive candidates for automobile paint.^[100] Figure 6d illustrates the design for a finger motion-sensing device based on a 1-D PhC design of an interpenetrated hydrogel network block copolymer with alternating water absorbable and non-absorbable lamellae which were found to be sensitive to relative humidity.^[101] The expansion of the hydrogel network in response to relative humidity caused a red-shift in the structural color of the film and the natural humidity of the human finger was capable of being detected by

the PhC film depending on the relative degree of proximity and motion. Arrays of these PhC films could even be used to detect the motion of a human hand using the same principle, creating a motion sensor based on the visual structural color appearance of the PhC film.

There are, of course, other emerging applications involving PhC films that hinge on the observation of a structural color. The vivid colors and iridescence association with PhC films make them particularly appealing for decorative designs for textiles,^[102–105] photonic glasses,^[106–108] and even wood surfaces.^[109–110] The freedom to tune the photonic response and structural color in PhCs also makes them suitable for encoding information, often through controlled wettability^[111–114] using a solvent, for applications involving anti-counterfeiting measures.^[115–117] Aside from the applications involving direct observation of a change to the structural color of a PhC, many research fields have specifically adopted PhCs for their ability to direct and alter the optical properties of structured materials. Nanostructures designed and applied to materials have been exploited for the photonic effects induced on the structure.

The proceeding sections will detail and review the mechanism of operation and application of PhC structures as applied

Applications of PhCs centered around the visual appearance of structural color. a) Electrical actuation of silica spheres in a cross-linked network of polyferrocenylsilane is shown to induce a redshift for structural swelling and the application of this technique to color display screens is demonstrated via a voltage induced redshift to the structural color of the PhC composite on indium tin oxide layers.^[94] Adapted with permission.^[94] Copyright 2007, Nature. b) Magnetic structural color tuning of superparamagnetic colloidal nanoparticles, achieved through magnetic field particle ordering, is shown for an applied magnetic field of 0.1 T for particles sizes SR = 200 nm, SG = 140 nm, and SB = 125 nm with structural color tuning demonstrated for anti-counterfeiting purposes where an applied magnetic field is a requisite for a visible color display.^[96] Adapted with permission.^[96] Copyright 2012, Royal Society of Chemistry.

to common research interests which specifically exploit and utilize the optical properties of the photonic bandgap or stopband in their application. Of course, other physical properties of these structures are often cited for their uptake and application to certain research areas and these will be discussed also. These would include an increased exposed surface area for improved electrochemical performance^[118,119] or photocatalysis reactions^[120,121] and the advantages of the scaffold architecture of these ordered structures to biomedical research areas such as tissue engineering or regenerative medicine.[122,123] For this work, emphasis is placed on the importance of the optical response of these ordered photonic materials by selectively examining applications with fundamental relations to the optical performance of the structured material. More specifically, the optical properties of PhCs will be examined in relation to their implementation in material sensor devices, solar cell technology, photocatalytic materials and waveguides in optical fibers. Principally, the design, understanding, and valid interpretation of the optical response of these materials will be shown to be crucial for the incorporation of PhCs in these areas of research.

2. Photonic Crystal Materials as Optical Diagnostic Sensors

One of the most prevalent applications of the optical behavior of PhC materials involves their ability to act as optical sensors, assessing a range of different material properties using the signature optical response of the ordered structure. The Bragg-Snell relation, as seen in Equation 4, allows wavelength shifts in the maximum wavelength position of diffracted light from the material to be predicted and interpreted. Optical sensors exploit the wavelength shift of the photonic bandgap

ADVANCED SCIENCE NEWS _____ www.advancedsciencenews.com or stopband to identify and assess changes to the material or material environment using the optical response of the structure. Typically, wavelength shifts in these structures are brought about by changes to the effective refractive index ($n_{\rm eff}$) or the interplanar spacing (d) of the structure. In alternating dielectric materials of refractive indices n_1 and n_2 occupying volume fractions φ_1 and φ_2 , the effective refractive index $n_{\rm eff}$ of the structure is commonly estimated by:^[80,89,124,125]

$$n_{\rm eff} = n_1 \varphi_1 + n_2 \varphi_2 \tag{5}$$

Combining this relation with Equation 4, an expression for all the factors influencing the maximum wavelength position of the photonic stopband is given by:

$$m\lambda = 2d\sqrt{(n_1\varphi_1 + n_2\varphi_2)^2 - n_1^2\sin^2\theta_1}$$
(6)

From Equation 6, the position of the photonic stopband is dependent on the interplanar spacing between layers, the angle of incidence and both of the refractive indices of the alternating dielectric materials. Porous materials, where the alternating dielectric consists of a high index material in a low index air background, are particularly suited to exploit this wavelength dependence on both the high index material (n_2) and the low index background voids (n_1) for optical sensor applications. Wavelength shifts associated with the photonic stopband can be used to identify materials, which can freely occupy void space in the structure, effectively changing the refractive index contrast of the PhC. Likewise, engineered changes to the interplanar spacing or refractive index of the high index material can also be used to diagnostically assess changes to the material system.

In terms of acting as an optical sensor, perhaps the simplest application of this analysis arises from material characterization for artificial opal and IO structures. For a known material, the wavelength position of the photonic stopband can be used to determine the size dimensions of the ordered structure from the interplanar spacing. This optical dimensional analysis has been frequently shown to accurately determine the size of the repeating structure, as compared with microscopy measurements.^[80,126,127] The appearance of the photonic stopband can also be used as an indicator of the degree of monodispersity present in the sample, with stronger scattering and lower optical transmittance associated with higher disorder and lower monodispersity.^[128,129]

IOs prepared using sol-gel methods from artificial opal templates are known to feature reduced lattice constants upon heating and inversion relative to the initial opal template.^[125,133,134] An optical assessment of the IO dimensions can provide a quick means to quantify any shrinking upon inversion. For 3D PhC structures, the information from the photonic stopband is relevant for the entire 3D surface interacting with incident light, whereas scanning electron microscopy assessment is largely limited to surface information. The photonic stopband is therefore ideal for nondestructively assessing any 3D structural anisotropy which might be present in the material.^[131] For known size dimensions, the optical information of the photonic stopband can, in principle, be used to assist in identifying the material comprising the PhC network. The refractive indices of materials, as determined from the optical stopband analysis, have been frequently used, in conjunction with other analytical methods, to determine the crystalline material of IO structures, even for composite or heterostructure materials.^[132–136] **Figure 7** provides an overview of some of the optical sensing and material characterization related to photonic stopband analysis.

In a broader sense, the optical sensing ability of PhC materials extends far beyond simple material characterization of the structures themselves. With proper calibration and knowledge of the optical spectrum, PhCs have been demonstrated to operate as excellent sensors for a range of different chemical substances. The photonic stopbands of SiO₂, ZrO₂, TiO₂, SnO₂, CeO₂ and Al₂O₃ IOs have exhibited a predictable and reversible shift of the principle diffraction peak upon the addition of various solvents to occupy voids in the structures.[80,124,125,137,138] The refractive index of the solvent and the Bragg-Snell relation proved to function as an excellent predictor of the wavelength shift observed for the photonic stopband. The transmission dips associated with the stopband red-shifted to longer wavelengths with increasing solvent refractive index. This spectral shift with solvent refractive index creates a sensing application, where the wavelength position of the photonic stopband in a properly calibrated structure can be used to determine the refractive index of a liquid infiltrating the PhC.

The sensitivity of this type of approach is particularly appealing for identifying mixtures or solution concentrations. TiO₂ IOs have been developed that are sensitive to various concentrations of ethanol solutions,^[139] with reported variations in refractive indices smaller than 0.002 yielding shifts in the stopband position greater than 1 nm.^[140] Similar work for ethanol solutions in WO3 IOs confirm the ability to optically sense the concentration of ethanol in binary ethanol/ water solutions.^[141] Solvent/water mixtures and their concentrations are particularly well studied for photonic crystal detection systems.^[139,142,143] More recently, some works have focused on developing photonic crystal sensors which offer a visual structural color indicator for the presence and concentration of particular solvents,^[144-146] with even the optical image intensity and peak absorbance linked to ethanol concentrations for SiO₂ IOs.^[147] Similarly, carbon IOs have demonstrated promising oil sensing capabilities with excellent response times and reversibility of the photonic stopband.^[148] The visual structural color of oil/gasoline and ethanol/gasoline mixtures has been exploited to indicate mixture concentrations in SiO₂ IO coated with hydrophobic fluoroalkylchlorosilanes.^[149] In this case, the appearance of the structural color is dependent on the wettability of the coated IO with respect to different concentrations of oil/gasoline or ethanol/gasoline.

Photonic stopband shifts are not limited to just liquid detection. Gas and vapor sensors have been developed using the principle of the spectral shift in PhC materials. Visual detection of volatile aromatic hydrocarbon vapors was achieved using a 1-D photonic crystal in which layers would swell, inducing a shift in structural color, when detecting compounds like benzene, toluene or xylene.^[150] SiO₂ IOs coated with polyvinyl alcohol display a spectral red shift with respect to the relative humidity in water vapor.^[151] The polyvinyl alcohol acts to swell in the presence of water vapor, altering the space between SiO₂ layers and leading to the red shift. A visual spectral red shift

of the photonic stopband of over 50 nm was recorded for SiO₂ IOs infiltrated with tetraphenylethene polymer in the presence of organic vapors of tetrahydrofuran and acetone.^[152] This red shift is attributed to an increase in the effective refractive index of the structure caused by the adsorption of the organic vapor by the polymer substance. Similar applications of polymer infil-

trated SiO₂ IOs have been developed for detecting aromatic volatile organic compounds such as xylenes.^[153] Likewise, spectral red shifts are proposed to arise from increases to the effective refractive index of the structure caused by adsorption of organic vapor by the polymer. **Figure 8** illustrates the stopband sensing capabilities for various IO structures to different analytes.

Specialized applications of PhC structures are present in PhC optical fibers, commonly used as sensitive refractive index sensors. PhC optical fibers and waveguides will be covered in more detail in Section 5. For now, emphasis will be placed on their ability to distinguish between small variations in refractive index. 2D PhC slabs with air holes etched in a square or triangular lattice into a slab of dielectric material, such as seen depicted in Figure 3c, are commonly used as the basis for a photonic waveguide. In simple terms, a waveguide is created when certain rows of the periodic structure are removed, e.g., air holes are selectively not-etched into a specific row(s) of the dielectric material. Light propagating in this region is confined by the photonic bandgap of the surrounding periodic structure in the plane of the PhC and total internal reflection effects of the optical fiber out of the plane of the plane of the slab. Defects introduced to the PhC regions act to create allowed modes for photon propagation in the photonic bandgap region of the structure. Defects can be introduced by removing holes or changing their radii in the repeating structure. The newly allowed photon propagation frequencies create an optical cavity in the defect region, introducing an optical confinement effect. Spectrally, these optical cavities appear as resonances with sharp dips/peaks on the optical spectrum of the PhC fiber. The wavelength position of these spectral features is strongly linked to the refractive index of the surrounding medium, through evanescent waves of the optical cavity interacting with the neighboring material of the fiber.

Figure 9. PhC fiber sensor designs for detecting a range of different substances. a) A seven cavity wide microcavity in a silicon-on-insulator wafer displaying a wavelength shift of 12.65 nm for a refractive index difference of 0.027 between water and ethanol.^[154] Adapted with permission.^[154] Copyright 2012, OPTICA. b) Air holes patterned into a silicon fiber sensor used to detect relative salinity in seawater.^[155] Blue-shifts in the confinement loss spectra correspond to higher salinity levels. Adapted with permission.^[155] Copyright 2018, Elsevier. c) A silicon-on-insulator PhC fiber with a smaller central cavity for light confinement is used to monitor anti-biotin levels in bovine serum by measuring the shift in resonance position with concentration.^[156] Adapted with permission.^[157] Copyright 2011, Elsevier.

The sensitivity of the resonant mode frequencies to the surrounding material has been exploited in PhC fibers for refractive index sensing, as seen in Figure 9. One or more of the air cavities in the PhC structure can be filled or continually pumped with an analyte which can be assessed via changes to the resonant mode wavelength. Calibration of a particular sensor design for multiple refractive indices should allow for accurate determination of analyte materials based on their refractive indices. The design of the optical cavity and waveguide will determine the spectral properties of the sensor. A seven-cavity (L7) wide defect in a silicon-on-insulator wafer has been demonstrated to feature a 12.65 nm shift in the resonant mode wavelength position when switching between water and ethanol, constituting a significant wavelength shift for a small refractive index difference of just 0.027.^[154] Salinity PhC fiber sensors, designed for detecting salt concentration in sea water, have been shown to detect salt concentrations in water via shifts in the resonant wavelength of confinement losses corresponding to minor shifts in the refractive index of salt water solutions ranging from 1.3326 to 1.3505 (0-100%).[155]

Biological processes such as protein binding can be monitored over time using this change in the refractive index of the resonant modes. The binding of anti-biotin to biotinylated-bovine serum albumin was monitored over time using the shift in resonance wavelength of the PhC fiber as an indicator of the anti-biotin concentration with detection sensitivity estimated at just 20×10^{-12} M of anti-biotin concentration.^[156] Similarly, PhC cavities functionalized with biotin were used to detect dissolved

avidin concentrations by monitoring resonant wavelength shifts with distinct peaks shifts observed at concentrations of 1 μ g mL^{-1,[157]} PhC sensors can also be specifically designed to detect a plethora of other material parameters, including temperature, curvature, pressure, strain, or electric field.^[158,159]

PhC hydrogels are increasingly common sensors designed to monitor and track changes to specific polymer infused PhC structures with a wide array of applications, particularly in biological and medical fields. Conceptually, the operation of these hydrogel systems is similar to the process of electrical actuation depicted in Figure 5a, where applied voltages increased the separation between PhC layers. Hydrogel systems used for optical sensing applications are typically designed such that the signature optical wavelength of the photonic stopband shifts in response to a swelling or contraction of the polymer medium upon exposure to certain chemicals or environmental conditions. Principally, it is the shift in the photonic stopband that allows a monitoring of the hydrogel material. The hydrogel polymer is selected to react with specific chemicals or biomolecules, creating a distinct optical response indicating the specific presence of reactant species.

Chemically, PhC hydrogels have been used as sensors to detect a number of different system properties. As previously discussed, humidity sensors were developed using polyvinyl alcohol embedded in SiO_2 layers.^[151] Polyvinyl alcohol hydrogel sensors have also been developed for pH detection, displaying a 350 nm wavelength shift of the photonic stopband position for pH values varying between 3.3 and 8.5.^[160] The hydrogel

www.advmattechnol.de

responds to increasing pH with an increase in the osmotic pressure of the polymer created when carboxyl groups are ionized and counter ions become immobilized in the hydrogel. The increase in osmotic pressure acts to swell the hydrogel, increasing the separation between polystyrene sphere layers and red-shifting the photonic stopband. This method of pH sensing was also found to apply to polyacrylamide hydrogels, where the swelling and shrinking of the gel caused by osmotic pressure was indicative of the pH and ionic strength of the solution.^[161]

ADVANCED SCIENCE NEWS _____ www.advancedsciencenews.com

Metal ions, such as Pb²⁺, Ba²⁺, and K⁺, could also be detected in similar systems by attaching crown ether molecules to the hydrogel networks which complexed with the metal cations and increasingly red-shifted the photonic stopband through increased osmotic pressure created with higher concentrations of metal ions binding to the crown ether.^[167] This hydrogel sensing method has been adapted for detecting various metal ions in systems, e.g., toxic mercury ions in water^[163] or toxic divalent beryllium (Be²⁺) ions in seawater.^[168] Immobilized urease in a hydrogel system was found to react with urea to produce NH₄⁺ and HCO₃⁻ ions which shrink the hydrogel, creating a blue-shift of the photonic stopband relative to the system in pure water. Hg²⁺ ions inhibit the urea reaction from proceeding inducing a relatively smaller blue-shift depending on the concentration of ions.

Outside of chemical applications, biomedical studies have adapted PhC hydrogels to respond to biomolecules, proteins, and viruses for the detection of monitoring of concentration levels. Polyacrylamide hydrogels functionalized with a creatinine deiminase enzyme and a 2-nitrophenol embedded in a polystyrene PhC structure have been demonstrated to function as a concentration sensor for creatinine levels in blood samples, a useful indicator in monitoring renal dysfunction.^[162] A redshift in the photonic stopband was linked to higher concentrations of creatinine, explained as an increase in pH resulting from hydroxide released from creatinine metabolism and an osmotic swelling of the hydrogel. Fungal microbes have also been detected by hydrogel systems. Candida albicans, a fungal microbe in which overgrowth in humans can lead to illnesses like pneumonia, was detected via a blue-shift in the photonic stopband related to a shrinking of the Concanavalin A protein hydrogels in a 2D PhC arrangement.^[164]

Hydrogel designs for detecting harmful organophosphate nerve agents, such as parathion, have been shown to detect ultratrace concentrations of organophosphorus compounds using the enzyme acetylcholinesterase.^[165] The magnitude of the photonic stopband red-shift was directly linked to parathion concentration in aqueous solutions arising from a swelling of the hydrogel network when the parathion molecules bind to the enzymes in the hydrogel. Glucose monitoring in polyacrylamide-polyethylene glycol hydrogel designs was achieved through a blue shift in the photonic stopband arising from increased hydrogel crosslinking related to the formation of a supramolecular complex created by glucose molecules selfassembling boronic acid and polyethylene glycol function groups on the hydrogel surface.^[169] Monitoring glucose levels is an important aspect of managing diabetes, with further works proposing non-invasive methods of monitoring of glucose in human tear fluid^[166,170] and urine^[171,172] or a minimally invasive methods using a microneedle wearable patch^[173,174] utilizing this colorimetric hydrogel detection method. **Figure 10** contains examples of the optical sensing capabilities associated with hydrogel PhC sensors.

There are many other emerging hydrogel PhC detection systems being researched with consistent innovation in the literature for a wide array of different detectable substances. Hydrogel PhCs have been developed as mechanochromic sensors with a colorimetric response to stretching or mechanical for use in wearable devices^[175] or as underwater motion detectors.^[176] The range of specific chemical compounds which can be detected by PhC hydrogel networks is always expanding with new reports of hydrogen peroxide,^[177] aldehydes,^[178] alcohol concentration in beverages^[179] or for drug delivery,^[180] thiol biomolecules^[181] and adenosine in DNA^[182] detection among recent works. Health-monitoring PhC hydrogel systems continue to be developed for detecting harmful residual antibiotics present in livestock milk,^[183] gram-negative bacteria such as Escherichia coli^[184] or Pseudomonas aeruginosa^[184,185] present in milk or drinking water, alkaline phosphatase enzyme levels as a marker for liver or endocrine diseases^[186] and metabolites such as L-kynurenine in blood as markers for immune suppressant disorders.^[187] Notably, all of these applications emphasize the importance of the sensitivity of the photonic stopband response and the presence of the structural color of the PhC as a visual indicator for changes to the ordered system.

3. Photonic Crystals in Slow Light Generation and Photocatalysis

The photonic bandgap or stopband associated with structured PhC materials can inhibit the transmission of certain frequencies of light, but we can also exploit the interesting optical phenomenon of slow light propagation occurring at frequencies close to the photonic band edges. Compared to bulk or non-structured films, it is the specific presence of the photonic bandgap/stopband that introduces slow photon effect. For a simple definition, the slow photon effect is a reduction in the group velocity of light as the light increasingly approaches the properties of a standing wave at energies close to the photonic stopband.^[188] This reduction in the group velocity (ν_o) of light can be visualized by a decrease in slope when approaching the bandgap/stopband in the dispersion relation diagram. Photonic band structure diagrams can be modeled for different types of PhC designs with various refractive indices or material filling fractions to predict the existence and energies of photonic bandgaps/stopbands.^[189–191]

Figure 11a displays band structure diagram for a TiO₂ IO, showing the existence of photonic stopband in the Γ -L direction, spanning the approximate wavelength range 380–450 nm.^[120] These band structure diagrams illustrate the allowed photon energies ($\omega(k)$) at different wavevectors (k). For light propagating through an isotropic, non-structured material, the dispersion relation can be written as;^[192]

$$\omega(k) = \frac{c_0}{n} |\mathbf{k}| \tag{7}$$

The group velocity at any point on these band diagrams can be found as:

$$\nu_g = \frac{\partial \omega}{\partial k} \tag{8}$$

The bending of the photonic band structure to accommodate for the photonic bandgap/stopband frequency range creates frequencies where the magnitude of this derivative is reduced, introducing the slow photon effect. The changes to the dispersion relation bands arising from a simple 1D PhC slab are shown in Figure 11b.^[192]

The reduction in the group velocity, as shown in the dispersion diagram, creates a scenario where the light, which is quickly approaching a standing wave, becomes more strongly localized in different dielectric regions of the material.^[188] www.advancedsciencenews.com

Slow light effects appear at either edge of the photonic bandgap/stopband region and the dispersion bands are often referred to as a dielectric (red edge) and an air (blue edge) band,^[193] as shown labeled in Figure 11c. With the slow photon effect, it is thought that the maximal amplitudes of the standing wave become more localized in different dielectric media when approaching from the red edge compared to the blue edge. Stronger localization of the light in the higher dielectric material is anticipated for the red edge of the photonic bandgap/stopband.^[188,193,194] Conversely, light localization for the lower dielectric material (air) is expected at the blue edge. A schematic representation of this effect can be seen in Figure 11d.

For PhC materials, the group velocity attenuation is dependent on the magnitude of the contrast between the dielectric materials, the structural quality, and thickness of the film.^[194] The slow photon effect in photon crystal materials has attracted much attention for applications where reduced group velocities and a targeted localization of light in specific materials is beneficial, particularly in photocatalysis applications. The direct relationship between photonic bandgap/stopband position and the slow photon effect allows the frequencies of the slow photon region to be tuned alongside the photonic bandgap/stopband, as depicted in Figure 12.

Photocatalysts are materials used in light-generated photochemical reactions where the photocatalyst (typically a semiconductor material) will generate reactive oxygen species stemming from electron-hole formation under light illumination. The photocatalyzed production of reactive oxygen species from the semiconductor acts to facilitate rapid reactions with other species in the reaction vessel.^[195] Major sectors where photocatalytic applications are explored are environmental waste/pollutant degradation,^[196–200] microbial disinfection^[201–203] and solar-fuelled energy production.^[204–208] A suitable electronic bandgap is a pre-requisite condition on the properties of semiconductors used as photocatalysts; redox potentials for the formation of reactive oxygen species and the evolution of hydrogen and oxygen from water should lie within the electronic bandgap of the semiconductor.^[209]

 TiO_2 is one of the most prominently used semiconductors in photocatalysis owing to a combination of its suitable bandgap, relative abundance, low cost, stability, insolubility in water, and nontoxicity.^[198,209] The basic operational principle for any photocatalytic material is the absorption of light at energies above the bandgap of the semiconductor, forming

Figure 12. a) A schematic diagram showing the blue and red-edge slow photon regions surrounding a photonic bandgap region^[194]; slow photon frequency ranges are directly related to the photonic bandgap position. electrons and holes. Photo-excited electrons promoted to the conduction band can react with oxygen species to form superoxide/hydroperoxide radicals and photo-generated holes in the valence band can oxidize water or hydroxyl groups to create hydroxyl radicals.^[210] These reactive oxygen species act to degrade other species present in the vessel, such as environmental pollutants, through oxidation and decomposition. **Figure 13**a displays a simple mechanism for photocatalysis

oxidation and reduction reactions in a material such as $\rm TiO_2$ with a bandgap below 390 nm. $^{[211]}$

ADVANCED SCIENCE NEWS _____

Although TiO₂ is widely used as photocatalyst on merit of its material properties, certain aspects of its semiconductor performance limit its ability for photocatalysis. Visible light-activated (VLA) photocatalysis relates to photocatalytic material designs which harvest the solar spectrum for catalytic reactions. The large bandgap of rutile TiO₂ (3.2 eV) and anatase TiO₂ (3.0 eV) requires UV light excitation for electron-hole generation; less than 5% of the solar flux incident on the earth's surface is located within this spectral range.^[209] Rapid charge recombination rates between photogenerated electron-hole pairs limit the quantum efficiency of photocatalytic processes in TiO2.^[210] Several strategies have been utilized by researchers in an attempt to move towards VLA photocatalysis by tuning the bandgap of TiO₂ towards the visible range, enhancing the absorption of the semiconductor in the visible range or suppressing the electron-hole recombination rate which limits the quantum efficiency.

Dye-sensitized photocatalysis relates to organic dyes acting as sensitizer molecules on the surface of the semiconductor, enabling absorption of visible light wavelengths by the dye molecules and the transfer of electrons from the dye molecules to the conduction band of the semiconductor. Colored, toxic organic dyes in wastewater, originating from industry sources like textile coloring,^[212] can be self-sensitizing by creating pathways for their own photocatalytic degradation under visible light.^[213] To enhance the performance of TiO_2 as a photocatalyst, other semiconductors have been interfaced with TiO₂ forming heterojunctions^[214] which can act to limit charge recombination^[215] and increase visible photocatalytic activity^[216] for correct choice of material. Noble metal nanoparticles with a surface plasmon resonance such as Au^[217] and Pt^[218] incorporated on the surface of semiconductors have shown reports of increased photocatalytic activity attributed to electron injection from the metal to the semiconductor, effectively inhibiting charge recombination rates and extending the absorption of the system into the visible range.^[219] Non-metals such as nitrogen,^[220] sulfur^[221] and carbon,^[222] have been explored as dopants for semiconductors as TiO₂ with reports of enhanced visible light photocatalysis. Schematic diagrams representing the mechanisms behind photocatalyst semiconductor modifications can be seen in Figure 13b-d for dye-sensitization,^[223] heterojunction^[214] and metal nanoparticle modifications,^[224] respectively.

IO PhC designs are frequently used in photocatalytic systems. The structural porosity and higher effective surface area of IOs make them attractive candidates for photocatalysts with reports of improved photocatalytic performances arising due to the effects of the structure.^[219,225] The optical effects associated with IOs, in particular the slow photon effect, have generated a lot of interest in photocatalysis research. As a controllable optical effect largely dependent on the structural size, the slow photon effect is often investigated in combination with other strategies, as described above, to enhance the photocatalytic performance of materials through a synergistic response.^[224,226-228] The reduced group velocity of light accompanying the slow photon effect is a desirable quality in photocatalysis; a decrease in group velocity leads to an increase in the effective optical path length of light which enhances light-matter interactions in the structure.^[194] Extending the active range of frequencies for photocatalytic semiconductor materials through engineered slow photon effects is also a possibility with IO designs. At first glance, it may seem counterintuitive to associate photocatalytic enhancement (improved or extended light–matter interactions) with a PhC material which acts to reflect light from a surface. A common strategy is to engineer the photonic bandgap/stopband frequency to coincide with regions of high absorption in the semiconductor, effectively suppressing the photonic reflection, while simultaneously locating the slow photon region in a spectral region of interest for enhancement.^[120,193]

For slow photon photocatalytic enhancement in IOs, some of the earliest investigations were focused on slow photon dye-sensitized systems.^[188,229] amplified Dye-sensitized degradation of methylene blue on an anatase phase TiO₂ IO was investigated by varying the size (tuning the photonic stopband) of the IO periodicity and also the angle of the incident light, effectively shifting the slow photon region between different samples.^[229] The largest enhancement factors for the photocatalytic degradation occurred when the slow photon red-edge overlapped with the incident monochromatic radiation, as seen depicted in Figure 14a. A separate study found that matching the absorption peaks of organic dyes such as methylene blue, rhodamine B and methyl orange to the stopband regions of various TiO₂ IOs enhanced the photocatalytic activity of the system under solar light illumination.^[230] The slow photon effect is credited with the enhancement of the dye-sensitization, as seen from the increased kinetic constants in Figure 14b.

Outside of TiO_2 other IO materials report similar slow photon enhancement effects. A ZnO IO was found to present the highest photocatalytic reaction rate for dye-sensitized rhodamine B photocatalysis when the red-edge of the photonic stopband overlapped with the ZnO electronic absorption band^[231] at higher angles of incidence. For the ZnO IO, the slow photon effect at the red-edge of the photonic stopband outperformed the blue-edge, as seen depicted in Figure 14c.

Hybrid structures of SnO2 IOs coated with nanocrystalline TiO₂ layers reported the highest rates of photocatalytic degradation of rhodamine B when the photonic stopband of the SnO₂ IO closely matched the electronic bandgap of TiO₂.^[232] A heterostructure design of a TiO₂ IO infiltrated with 10 nm Cu₂O nanocrystals reported an increase in the photocatalytic degradation of rhodamine B and bisphenol A under UV-visible wavelengths when the slow photon region overlapped with the optical absorption of the Cu₂O nanocrystals,^[233] as shown in Figure 15a. Increased photocatalysis in this case was attributed to the synergy of the increased charge separation resulting from the heterostructure and the slow photon effect enhancing the light harvesting of the system. Similarly, a heterostructure of an SnO₂ IO with CdS quantum dots deposited uniformly over the surface of the IO reported increased rates for the removal of carbamazepine,^[234] again attributed to a combination of the heterostructure and the slow photon effect as seen in Figure 15b.

The photocatalytic synergy between noble metal modification of semiconductors and the slow photon effect has also been explored. 2.3 wt% of Pt nanoparticles deposited on the surface of a TiO₂ IO demonstrated an enhancement of the photodegradation efficiency of acid orange by a factor of four.^[226] Neither the slow photon effect from the IO structure or the enhanced charge

separation from the Schottky barriers at the TiO_2 -Pt interface alone was sufficient to achieve this enhancement; the cooperative effects were needed to record the greatest enhancement factor. For improved performances in the visible spectrum Au nanoparticles have been deposited on TiO_2 IOs for photocatalytic degradation of 2,4-dichlorophenol using a combination of the TiO_2 –Au heterojunction for charge separation, the slow photon effect of the IO and the increased light absorption in the vis-

ible from the localized surface plasmon resonance of the Au nanoparticles.^[219] This combination effect can be seen from the data depicted in Figure 15c. These strategies for enhancing the photocatalytic performance of semiconductors through a combination of the slow photon effect with other existing methods are currently of great interest for photocatalysis research.

Recent works with visible light and Au nanoparticles incorporated onto $\rm ZnO^{[227,235]}$ or $\rm V_2O_5^{[224]}$ IOs are further examples exploring this synergy of photocatalytic effects. The placement of Au particles in TiO_2 IOs and the role of slow photons in synergistic photocatalytic effects have also been studied.^[236] Many emerging slow photon works focus on IO heterostructures,

www.advmattechnol.de

where two semiconductor materials are placed in contact to improve light harvesting effects in conjunction with slow photon effects. For photocatalytic CO₂ reduction, a rheniumdoped TiO_{2-x}/SnO₂ IO heterostructure^[237] and CeO₂ nanolayers supported by a TiO₂ IO^[238] have been investigated. Similarly, a TiO₂/graphitic-C₃N₄ IO heterostructure showed an enhanced performance for rhodamine B degradation^[239] and Bi₂WO₆/WO₃ IO heterostructures with graphene quantum dots enhanced phenol degradation.^[240] Recent prevailing opinions^[241-244] emphasize that high quality, structurally scalable and mechanically stable inverse opal films with a strong optical signature are crucial for maximizing the slow photon effect. It has even been suggested that higher order slow-light modes found only in high quality TiO₂ IO films may be more efficient at light trapping than traditional red and blue-edge of the photonic bandgap.^[242]

4. Photonic Crystals in Solar Cell Devices

Solar cell devices operate under the principle of photovoltaic energy conversion under which electromagnetic radiation is converted into electrical energy. The process of electrical energy conversion can be described as light absorption by an absorber material creating a transition from ground to excited state, production of an electron and hole from this transition, charge migration of the electron through an external circuit from cathode to anode and recombination of the electron with a hole to return the absorber to the ground state.^[245] Thick, crystalline silicon-based solar cells have been the dominant photovoltaic devices in solar cell technology for quite some time. Silicon solar cells are popular due to the abundance of silicon available in the earth's crust, the non-toxicity of the material, the proven efficiency and stability of the technology and the semiconducting properties of silicon were widely studied.

Limitations on conventional silicon solar cells are known and were predicted;^[246,247] the indirect bandgap of crystalline silicon necessitates thick layers of silicon for efficient cells and the high associated cost of manufacturing thick layers of crystalline silicon created an economic impediment. Research trends in solar cells have been focused on driving production costs down, minimizing energy usage and environmental CO₂ emissions^[248] from crystalline silicon production while attempting to preserve or improve on the efficiencies of the silicon solar cell. Thin-film silicon solar cells,^[249] thin films of alternate materials like cadmium telluride or copper-indium diselenide,^[250] organic solar cells,^[251] perovskite solar cells,^[252] and dye-sensitized solar cells^[253] are among some of the alternative classes of solar cell being researched for future implementation.^[254-256] Here, we discuss the role of PhC materials, specifically their optical properties, which have been used to enhance the performance of certain classes of solar cell.

Thin film solar cells have been researched as alternatives to the thicker crystalline wafer silicon solar cells. Hydrogenated amorphous silicon (a-Si:H) and hydrogenated microcrystalline silicon (μ c-Si:H) are common examples of silicon thin films used in these solar cells; the thin films of these materials offer the potential advantages of cost reduction in material preparation and are much quicker to pay back the energy input required

to fabricate these devices.^[259] Direct bandgap semiconductors like cadmium telluride or copper-indium selenide species feature much larger absorption coefficients allowing for higher absorption of incident photons over a shorter distance, such as a thin film.^[260] Amorphous semiconductors with an indirect bandgap (such as a-Si:H) tend to feature larger absorption coefficients^[261] when compared to their crystalline counterparts due to the structural disorder in the amorphous material relaxing the quantum mechanical selection rules for absorption.^[259] In spite of a larger absorption coefficient, amorphous silicon features a wider bandgap (≈1.7-1.9 eV for a-Si:H) compared to crystalline forms of silicon (≈1.1 eV), limiting the amount of the solar spectrum absorbed by the amorphous material.^[262] Micromorph or tandem solar cells featuring heterojunctions of a-Si:H and µc-Si:H have been developed to promote increased absorption at longer wavelengths and limit light-induced degradation of the amorphous material.^[262,263]

Increasing the absorption of the semiconductor material is key to improving the performance of thin-film solar cells. A widely used technique in thin-film solar cells is light trapping, which uses material or layer modifications to increase the path length of light in the absorbing material thereby increasing the probability of absorption.^[264,265] Light trapping techniques are essential for thin-film cells in particular as the absorbing layer is nominally short. The front surfaces of layers in the solar cell are often textured to promote scattering and total internal reflection effects which extend the path length of light in the material.^[265,266] Back reflectors, textured metal surfaces separated from silicon layers by a thin dielectric layer,^[267] are also used to reflect incident light and create longer path lengths. Figure 16a illustrates this effect where textured surfaces are utilized to confine light to the absorbing semiconducting layer. In thin film solar cells, PhCs find their application here by providing controllable and enhanced reflections from material lavers to promote increased absorption.

A 1D PhC material of alternating dielectric layers of sputtered indium-tin oxide and SiO₂ layers has demonstrated potential for application in integrated photovoltaics, where semi-transparent solar cells for use in windows or skylights are designed using a back reflector of a conducting PhC in place of a metal layer for light trapping in thin-film cells.^[268] The tunable reflections in the photonic structure can be modified by adjusting the layer thicknesses to selectively reflect specific wavelength ranges while transmitting the remainder of the spectrum for light or heating; in this case, wavelengths above the absorption edge of the a-Si:H thin-film were reflected to boost performance. The device structure and performance for these 1D photonic solar cell back reflectors can be seen in Figure 17a.^[268] Another application involving alternating 1D PhC dielectric layers of silicon nitride and silicon oxynitride integrated into a crystalline silicon solar cell is based on aesthetically designing colored solar panels using the reflected wavelengths from the PhC for uses in smart design and green building.^[269] Red, blue, green, and white solar cell panels were fabricated by adjusting the thicknesses of the dielectric layers deposited on the glass to tune the reflectivity of the photonic bandgap, as seen in Figure 17b.^[269]

3D PhCs in the form of silicon IOs have also been incorporated as back reflectors in crystalline silicon thin-film solar cells with a reported increase in the light trapping of the solar

cell resulting from the IO back reflector.^[270] Photonic bandgap reflections, pseudogap regions, diffuse back scattering and surface diffraction effects in the IO material were all factors believed to contribute to the performance enhancement of the IO back reflector versus a back reflector of aluminum; the IO reflection could also be tuned to the near-IR region where it is most needed for crystalline silicon solar cells. The IO back reflector solar cell was also combined with surface texturing, showing improved absorption using a combination of these effects as seen in **Figure 18**a.^[270]

www.advancedsciencenews.com

PhC materials also find application in thin-film solar cells as intermediate reflector layers in tandem solar cells. Tandem solar cells often suffer from current mismatch between the absorbing layers in the solar cell and intermediate layers are often included in an attempt to equalize the current generated from each laver. In the case of a micromorph silicon tandem solar cell, the a-Si:H top layer emits a lower current compared to the μ c-Si:H bottom layer. This limits the overall efficiency of the solar cell and intermediate layers are included in an attempt to equalize the current generated by spectrally splitting and reflecting the spectrum.^[271] A ZnO:Al IO in a tandem solar cell between a-Si:H and μ c-Si:H layers reported an enhancement factor of 3.6 in the external quantum efficiency of the limiting a-Si:H layer by acting as wavelength selective filter; high energy wavelengths were reflected back into the a-Si:H layer using the photonic bandgap and lower energy wavelengths were transmitted to the μ c-Si:H layer for absorption.^[272] The IO intermediate layer was reported to outperform other intermediate layer materials such as thin-film based intermediate layers, the results of which can be seen in Figure 18b.

A separate class of solar cell devices that have seen an increased uptake of PhC materials are dye-sensitized solar cells (DSSCs). The operating principles of DSSCs are fundamentally similar to the dye-sensitized photocatalysis mechanism discussed in Section 3. In DSSC systems, the production of electricity from light can be thought of in terms of a cycle of reactions as shown in Figure 16b.^[258] Photoanodes, such as mesoporous TiO₂, are deposited on transparent conductive substrates and sensitized with dye molecules to harvest light. A circuit is connected from the photoanode to a counter

electrode, such as platinum-coated conductive glass, and an organic electrolyte containing a redox couple, commonly I^-/I^{3-} , separates the electrodes.^[253] Photoexcited electrons generated from dye absorption are transferred to the conduction band of the semiconductor, collected by anode, transported through an external circuit to perform work and arrive at the counter electrode. Sensitized dye molecules, after transferring electrons, are reduced by the electrolyte and in turn the electrolyte absorbs the electrons which arrive at the counter electrode.^[253,258]

Unlike the photocatalysis reactions which act to degrade or eliminate dye molecules or other species in the reaction vessel, DSSCs operate by regenerating the dye species using an electrolyte and closed circuit such that no material is lost or converted and the cycle can continue to generate electricity. Compared to conventional crystalline silicon solar cells, DSSCs are cheaper, easier to fabricate, more flexible, feature a higher sensitivity to low-intensity environments and have the potential to possess a low environmental impact with respect to material choices.^[253,273] Low efficiencies, long-term stability, and material production costs of DSSCs hinder their economic viability.^[273] The most successful DSSCs with the highest efficiencies tend to feature Ru-bipyridyl compounds as sensitizer molecules which have a high associated cost, time consuming production steps and is a toxic material^[258,274,275] and presently natural alternatives do not offer comparably high efficiencies.^[274,276] For all manner of DSSCs research methods to improve the efficiency of light absorption through cell design or material choice are an essential consideration. With regards to the photoanode material, methods to improve the light-harvesting efficiency are based on increasing surface area, dye molecule pickup, reducing charge recombination, improving electron charge transport and increasing the light scattering ability to increase absorption.[253,277,278]

PhC materials find application in DSSCs as a means of promoting scattering and reflection effects for light incident on the photoanode. Typical photoanodes in TiO₂ DSSCs consist of a layer of mesoporous TiO₂ nanoparticles with a large surface area loaded with dye molecules. TiO₂ IOs with photonic stopbands in the visible range acting as the electrode in DSSCs were found to underperform compared to nanoparticle anodes,

attributed to the superior dye loading ability of nanoparticle layers;^[282] however, the potential of the IOs to act as tunable dielectric mirrors to enhance dye absorption was highlighted. Different PhC configurations have been explored in conjunction with mesoporous TiO₂ electrodes to establish an improvement in the light harvesting ability of the photoanode using the optical properties of the PhC as a reflector or scattering region. Porous 1D PhCs, consisting of alternating layers of SiO₂ and TiO₂, deposited on the back surface of a nanocrystalline TiO₂ photoanode were shown to enhance power-conversion efficiency in DSSCs; the porous PhCs allowed the electrolyte to interact with dye molecules in the inner layer.^[279] Both 1D PhC materials with different photonic stopbands were found to provide an enhancement of the current density; the largest enhancement was achieved when the peak reflection of the PhC matched closest to the absorption band of the ruthenium dye, as seen in Figure 19a.

Similar effects were observed with 2D TiO2 nanotube PhCs prepared on the back surface of a dye-sensitized TiO₂ nanoparticle layer.^[280] All PhC nanotube structures were found to enhance the power-conversion efficiency when compared to non-PhC nanotubes or nanoparticle photoanodes fabricated at identical thicknesses; the enhancement effect was most pronounced for matching the PhC reflection with the maximum dye absorption.^[280] Figure 19b displays the structure and performance enhancement of the nanotube PhC. 3D silicon IOs when successfully deposited onto nanocrystalline TiO2 and ZnO nanowire electrode layers also demonstrated enhanced light-trapping in DSSC systems.^[281] Reflections from the pseudo-photonic bandgap of the electrolyte-infiltrated silicon IO enhanced the current density recorded for the DSSC, as observed in Figure 19c. A large impediment to 3D PhC incorporation into a DSSC is the fabrication of high-quality films on the mesoporous TiO₂ surface, though successful examples do ADVANCED SCIENCE NEWS _____ www.advancedsciencenews.com

exist in the literature.^[281,283,284] Multilayers of IOs with differing lattice constants and optical responses have also been suggested for further spectral light harvesting in DSSC systems^[285] with a two-layer IO system reporting an enhancement in a TiO₂ DSSC.^[284]

Finally, IO materials have also been explored in solar cell devices in order to exploit slow photon effects. The reduced group velocity of light at the photonic band edge has the potential to increase light-matter interactions, see Section 3 for more details. Inverse crystalline silicon opals treated with hydrogen plasma passivation demonstrated increases in the enhancement ratio of the internal quantum efficiency of the silicon solar cell at wavelengths close to the photonic bandgap and band edges.^[286] This amplification in the photon-to-electron conversion efficiency around the photonic bandgap regions was

attributed to slow light trapping effects, as seen in **Figure 20**a. Large-area and high-quality IO WO₃ photoanodes were found to exhibit large increases in the photon-to-electron conversion efficiency compared to disordered porous and unpatterned non-porous WO₃ electrodes.^[288] Between the various IO sizes tested, the largest enhancement was observed when the red edge of photonic bandgap overlapped with the WO₃ electronic absorption edge, as seen with the WO₃-260 sample in Figure 20c.^[288]

Quantum dot sensitized solar cells, where quantum dots are used as absorber sensitizers on semiconductor films, also feature reports of slow photon enhancement effects. TiO₂ IOs sensitized with quantum-confined CdSe films displayed a significant amplification of the photon-to-current conversion efficiency with an average enhancement factor of 6.7 ± 1.6 at 640 nm for an IO structure with a photonic bandgap at

700 nm compared to a nanocrystalline TiO₂ with similar CdSe sensitization.^[289] This enhancement was attributed to a blueedge slow photon effect overlapping with CdSe absorption edge (600–650 nm). More recently, CdTe/CdSe quantum dot sensitized TiO₂ IOs were shown to feature a fourfold enhancement factor of the photon-to-current conversion, compared to nanocrystalline TiO₂ films, when the blue or red-edge of the photonic stopband was tuned to match the quantum dot absorbance edge.^[287] Smaller gains in the enhancement factor were noted for quantum dot absorbance edges centered in the photonic stopband compared to blue or red-edge effects, heavily suggesting a slow photon amplification effect. Figure 20b displays the slow photon enhancement factor for both CdTe/CdSe and CdTe quantum dots on TiO₂ IOs.

These are just some of the strategies combining the optical performance of PhC layers with the light harvesting capabilities of semiconductors materials and sensitizer molecules present in solar cell devices. Optically, the PhC layers in solar cells are often used to promote light absorption through targeted reflectance of specific wavelengths and improving the path length of light through the cell. Some recent works^[290-292] have attempted to determine the effects of the angular iridescence response of the photonic signature associated with PhCs on solar cell performance, simulating more realistic operating conditions with the changing position of the sun. Other works are focusing on the aesthetic capabilities of PhCs in solar cell devices with a wide range of tunable structurally colored designs options available for decorative purposes in solar cells which incorporate PhC layers.^[293-296] Solar cells featuring controllable PhC structural color are often explored as candidates for smart window designs.^[269-298] Current research trends appear point toward both a functional and aesthetic role for PhCs in solar cell devices.

5. Photonic Crystals in Waveguides and Optical Fiber Designs

Optical waveguides are structured materials designed to transport energies, typically in the visible or infrared regions, between a source and destination. Waveguides are designed to guide light based on how light interacts with different regions of the material. The theory and optics behind traditional optical waveguides are quite well understood.^[299] In general, a traditional optical waveguide will consist of a high refractive index core material, surrounded by a lower refractive index cladding, all encompassed by a protective jacket. Waveguides with this design are commonly called optical fibers. Light is guided from one end of the fiber to the other using the principle of total internal reflection (TIR) between different refractive index regions of the fiber. The constraint of a high index core material is introduced from this mechanism of light guiding; waveguides relying on TIR confine light to the core region of the fiber only if TIR can occur, i.e., the core refractive index must exceed the cladding refractive index. The angle

Material constraints and light guiding mechanism in an optical fiber operating c) as a waveguide where total internal reflection occurs for chosen refractive indices and propagating angle and d) without a waveguide where light refracts through the cladding due to a lower core refractive index or angles smaller the critical angle.

at which the light enters the core region must also exceed the critical angle for TIR effects to be observed. The typical structure and waveguide mechanism for light in an optical fiber are shown in **Figure 21**a–d.

Optical fibers are a widely used technology across many different fields of study. Flexible fibers are ideal for imaging internal organs in medicine,^[301,302] optical fiber lasers have been developed with doped cores to control the refractive index and photon absorption^[303,304] and optical fiber refractive index sensors and their applications were earlier discussed in Section 2. The most critical application of optical fiber waveguides is found in optical fiber communication technologies where nearly two billion kilometers of optical fiber are used for telecommunications and data transfer.^[305] Internet connections and phone reception are dependent on high speed data transfer and the associated low cost of optical fibers. The conventional waveguide design by TIR is not without its challenges. Most optical fibers use silica glasses in their composition, linking the optical transparency and absorption to the material properties of silica. Silica is transparent in the visible and near-infrared regions yet prone to high attenuation in the mid-infrared and ultraviolet regions.^[306] Silica-based fiber optical cables of this design are also limited by small refractive index contrasts of the core and cladding material which need to be thermally compatible and the nonlinear optical response of the silica core limits the amount of light which can be transferred.^[307] Conventional silica-based optical fibers are designed with a careful balance between optical material losses and nonlinearity effects and years of refinement of fiber design has pushed the fabrication technology to close to the innovative limit for these structures.^[307,308]

PhC fibers are a separate class of optical fiber emerging in optical fiber research since the first demonstration of a silica core surrounded by a silica–air PhC fiber in 1996.^[309] PhC fibers were proposed as alternatives to traditional optical fibers, specifically for applications outside of optical communications where standard fibers failed to meet demands such as higher power transport, optical sensing, engineered dispersion, and nonlinearity.^[310] PhC fibers make specific use of the photonic bandgap in ordered structures to guide light along the waveguide. Typically, PhC fibers are categorized as solid or hollow core fibers depending on the composition of the waveguide. The mechanisms for light guiding in these structures are drastically different, as are the associated applications with each fiber. Solid core fibers are reminiscent of the conventional optical fiber design and function, while hollow core fibers represent a departure from the traditional optical waveguide mechanics used.

First looking at solid core designs in PhC fibers, as depicted in **Figure 22**, TIR governs the waveguide mechanism just as with standard optical fiber cables. The earliest PhC fiber designs were solid silica core structures surrounded by a PhC composed of a silica and air matrix with an incomplete photonic

Figure 22. a) A solid core silica PhC fiber cross-sectional image, showing a hexagonal PhC arrangement of five rings of air holes surrounding a silica core in a labeled schematic diagram.^[311] Reproduced with permission.^[311] Copyright 2019, OPTICA. b) A microscopy image of a solid core 125.3 μm fiber with an average hole diameter of 4.79 μm and an average pitch of 9.97 μm.^[312] Adapted with permission.^[312] Copyright 2006, OPTICA & IEEE Photonics Society. c) The light guiding mechanism in solid core PhC fibers is shown governed by total internal reflection effects for angles larger than the critical angle.^[307] Refraction effects prevent waveguide formation at angles below the critical angle. Adapted with permission.^[307] Copyright 2002, American Association for the Advancement of Science.

bandgap.^[309] Light is confined to the core region of these fibers by TIR effects between the silica core of higher refractive index and the silica PhC with a much smaller effective refractive index due to the presence of air holes. The increase in refractive index contrast between the core and cladding affects the dispersion in these fibers, enabling the creation of a single-mode broadband optical continuum over the visible range.^[313]

Ultra-flattened, near-zero dispersion has also been achieved in the infrared region of solid core structures with precise control over the hole shape, size, and core diameter.^[314] The birefringence of the fiber can also be engineered in the structure by altering the air capillary thicknesses surrounding the silica core, creating birefringent effects up to ten times stronger compared to conventional optical fiber designs.^[315] Larger core diameters supporting only a single mode are also possible, provided the shape and geometry of the PhC fiber are conserved.^[316] Larger effective core diameter designs allow for higher power applications while reducing nonlinear effects.[317,318] Many of these effects can be engineered in fibers depending on the specific application. For example, supercontinuum light sources are feasible with PhC fibers due to the higher power output, broad spectral bandwidth and the control over nonlinear effects with applications in optical coherence tomography, spectroscopy and frequency metrology.^[319–321]

Hollow core PhC fibers operate on with a fundamentally different mechanism for guiding light. Hollow core fibers are generally formed as an air core surrounded by a 2D PhC structure. The first demonstration of a single-mode hollow core fiber structure was of an air core surrounded by a silica-air PhC.^[322] Waveguides in hollow-core fibers are created using the complete photonic bandgap of the cladding around the central air core. Specific frequencies of light are confined to the core based on the coherent Bragg reflection from the PhC cladding. Importantly, TIR effects are not occurring in hollow-core fibers as the refractive index of the air core is strictly lower than the surrounding material; light is guided by photonic bandgap reflections only. This distinction in waveguide mechanics has led to the term photonic bandgap fiber often being used to describe hollow core fibers. Light traveling along a hollow-core fiber is unique compared to other fiber designs as it does not need to transport through a solid material, like silica. As a result of this, 99% of the optical power in these fibers travels through air instead of silica glass removing the fundamental scattering and absorption processes associated with glass waveguides.^[323] The absence of the solid core loss mechanisms and reduced optical nonlinearity effects make hollow core fibers attractive candidates for low loss fiber designs.^[323,324] Typical designs of hollow core PhC fibers can be seen depicted in Figure 23.

Hollow core fiber designs present many opportunities and applications compared to traditional optical fibers. The reduced nonlinear response and absorption of an air core compared to a silica core is reported to reduce the Kerr response (nonlinear refractive index changes) of the fiber by a factor of up to 1000.^[327,328] This reduction in nonlinear effects has led to the development of anti-resonant hollow core fibers used for transporting high power ultrashort laser

pulses^[306,325,328,329] without lengthening the pulse duration, reducing the peak intensity or incurring damage to the fiber, as experienced in conventional silica core waveguides. Ultrashort laser pulses have practical applications in areas such as micromachining^[330] and biomedicine.^[331,332] Hollow core PhC fibers are also ideal for transporting wavelengths of light which fall outside the silica transparency window. Silica is prone to damage from UV wavelengths; anti-resonant hollow core fibers can better transport UV light due to significantly reduced interactions between the guided light and solid material in the PhC cladding.^[306,333] While mid-IR waveguides in solid core fibers can be achieved by using modified chalcogenide glasses in the fiber design, hollow core fibers have the advantage of being less fragile and transmitting deeper into the infrared.^[334]

One area which has exploited the photonic bandgap confinement in hollow-core fibers is nonlinear optics.^[335] The design of hollow core fibers allows a tailored nonlinear optical response depending on the application; air-filled fibers with low intrinsic nonlinearities are ideal for transporting high power pulses and liquid or gas-filled fibers can create high levels of nonlinearity for low power frequency conversion effects. Nonlinear materials, such as liquids and gasses, can also be introduced into the hollow core region for specific applications requiring increased light path lengths, high intensities, high optical damage threshold and a controlled group velocity dispersion by alteration of the pressure.^[336] Argon gas-filled hollow core PhC fibers have demonstrated a capability of acting as bright, spatially coherent and wavelength tunable UV laser sources using the nonlinear response of a 27 μ m gas-filled fiber when pumped with IR ultrashort pulses.^[337] Variation of the pulse energy and Ar gas pressure allowed the wavelength of the UV light produced to be tuned between 200 and 300 nm with conversion efficiencies up to 8%.

A follow up study^[338] found that the gas could also be changed resulting in optical frequencies for Xe and Kr and a deeper UV signal for Ne, as seen in Figure 24a. Low threshold stimulated Raman scattering is another example of an application of hollow core fibers. Using photonic bandgap guided light in hollow-core fibers, frequencies were filtered in light interacting with H₂ gas, suppressing stronger vibrational modes and allowing the observation of weaker rotational bands at energy thresholds up to 10⁶ lower than previous observations.^[339,340] Varying the pump polarization further allowed the Raman output spectral components to be controlled, as seen in Figure 24b. Lastly, there have even been reports of utilizing the slow photon effect in conjunction with nonlinear optics in PhC waveguides.^[341] Enhancements of self-phase modulation induced spectral broadening of output signals and two photon absorption^[342] alongside delayed transmissions of picosecond optical pulses^[343] are some examples of effects being attributed to slow photon behavior in 2D silicon waveguides.

Recent studies with PhC fibers, primarily hollow core designs, are exploring the vast range of analytes, which can be detected using PhC fiber sensors. Sensors for chemical and biological species are consistently emerging from the literature. Gas sensors for CO_2 ,^[344] $N_2O^{[345]}$ and CH_4/HF ,^[346] chemical sensors for kerosene concentration in fuel^[347] and detecting illicit drugs,^[348] health monitoring biosensors for glucose^[349] and cholesterol^[350] and health diagnostic sensors for detecting various

types of cancer cells^[351–353] are among some of the emerging applications for PhC fiber sensors. Some PhC fiber sensor research aims to improve the selectivity and sensitivity of detections by combining the waveguide mechanism of the fiber with the surface plasmon effect,^[354–356] incorporating metal particles or thin metal layers into the fiber to enhance detection sensitivity. Other research works investigate the material used to fabricate the fiber to identify optimal operating conditions

with thermoplastic polymer materials, such as Zeonex and Topas, showing promising applications for Terahertz frequency ranges.^[357,358] Emerging graphene-based PhC fibers are being explored due to graphene's high surface to volume ratio, low associated cost with simple synthesis and its ability to protect against oxidation of metals (e.g., Ag) with its high electron density preventing molecules from passing through the ring-like structure for surface plasmon applications.^[359–361]

6. Photonic Crystal Structural Porosity and Interconnectivity Applications

Thus far, the wide array of optical applications for PhC materials have been discussed across several disciplines. When discussing optical implementation, the ability of the material to attenuate, tune or reflect incoming light is a major consideration for the incorporation of repeating structured dielectric lavers; the role of the structure is to provide the required optical response. Beyond optical applications, PhC materials have found practical uses relating to their structure alone. 3D PhC structures, such as IOs in particular, are often prepared for the porous interconnected structure of crystalline material as opposed to any optical considerations. In many cases where the structure of ordered material is central to its implementation, IOs and other 3D PhCs are often classified as three-dimensionally ordered macroporous (3DOM) materials.^[90,362,363] From a structural standpoint, some of the attractive qualities of 3DOM materials include an increased surface-to-volume ratio compared to bulk materials, a bicontinuous material with an interconnected solid material and an interconnected pore system, efficient mass transport trough the structure with low tortuosity and relatively large pores to allow for surface functionalization of the material walls.^[91,364] For porous structures, the simplicity and inexpensive size-controlled fabrication method for IOs alongside the wide range of compatible materials add to the appeal of using IO 3DOM materials versus other ordered porous materials.[365] In this section, applications involving the structure of 3DOM materials are discussed to shed some light on the potential benefits arising from utilizing materials like IOs other than their ability to modulate light propagation.

IO materials have emerged as ideal structured candidates in certain areas of biomedicine.^[122,123] In general, the scale of these types of IO materials is much larger than their photonic counterparts with pore sizes of around 100 um. However, the colloidal crystal templating and inversion procedure are identical, producing structurally similar IO materials, albeit with larger repeating lattice sizes etc. The role of IO materials in biomedical research is to act as structural scaffolds or biomimetic supports with an ordered and interconnected surface: purely a structural function with no optical component. In biomedicine, the area of cell culturing and tissue engineering has explored the benefits of IO materials as structural supports. Tissue engineering involves transplanting a biofactor (cells, genes, or proteins) into a porous degradable material scaffold; the scaffold acts to provide temporary mechanical support and deliver the biofactor throughout so that the regenerated tissue assumes function as the scaffold degrades.^[366] Aside from initially supporting the cells and aiding in their proliferation, the architecture of the porous support ultimately decides the shape of the newly grown tissue in an ideally reproducible and economically viable large scale.^[367]

A major factor found to influence the reproducibility and the homogeneity of cells grown across the porous scaffold is the uniformity of the scaffold material, with uniform IOs outperforming structures with nonuniform pore sizes in terms of diffusion of macromolecules and the uniformity of the fibroblast cell distribution in the IO scaffold,^[368] as seen in **Figure 25**a. Nonuniform pore structures can produce regions with

insufficient concentration of nutrients for cells, inhibiting homogenous tissue formation. In this case, gelatin microspheres, prepared via sedimentation evaporation, were used as the sacrificial template and infiltrated with PGLA under vacuum suction to form the IO structure. A common IO material used in tissue engineering is poly(D,L-lactide-co-glycolide) (PLGA),[368,369,370] a polyester material approved for clinical trials with a controllable degradation rate depending on the lactic and glycolic acid ratios used in preparation.^[371] A study of PLGA IOs found that the pore and window (interconnected circular openings between adjacent pores) size of uniform IOs had an effect on the physical properties (compressive moduli) and migration depth of cells in the IO scaffold.^[369] Larger pores and windows featured a greater migration depth of cells with a lower compressive modulus. PLGA IO scaffolds with gradations in hydroxyapatite (HAp) nanoparticle minerals allowed for a spatial control of cells grown across the scaffold, potentially beneficial for emulating connective tissue-to-bone interfaces.^[370] Outside of PLGA IOs, chitosan^[372] and silk fibroin^[373] IO scaffolds have also been investigated for tissue engineering. For the silk fibroin IO scaffolds, the ordered geometry of the IO structure was found to promote almost double the mineralization of human mesenchymal stem cells compared to a silk fibroin scaffold prepared with a similar average pore diameter by salt-leached processes,^[373] as seen from calcium concentrations in Figure 25b. In more recent works, hydrogel IO systems have been used as targeted drug delivery systems with drug release controlled by application of NIR radiation for wound healing^[374] or spinal cord repair.^[375] Anisotropic IO structures, deformed by stretching an axis in a particular direction, have been utilized to direct the orientation of cell growth for controlling nerve cell growth^[376] and preventing skin scar formation.[377]

The macroporous structure of IO configurations has also attracted some attention for its potential to act as a separation or filtering membrane. Specifically, 3DOM IO structures with highly interconnected and regular pore sizes have been explored as microfiltration^[378] or ultrafiltration^[379] separation membranes. Porous membranes are often used in filtration systems where the membrane attempts to remove particles suspended in a liquid, with water purification being a prime example of the process. Porous membranes are often investigated in terms of the separation efficiency (the efficiency at which particles are removed) and the permeation flux (the stable rate at which a liquid feed can be processed). An enhancement of the separation efficiency often results in a decrease of the permeation flux and vice-versa. 3DOMs are appealing as separation membranes due to their high pore uniformity with the potential to act as highly selective separators for desired species.^[380] The ability to tune pore size in fabrication allows the sizes of filtered particles to be controlled while an interconnected pore system in a membrane is advantageous for establishing a slower rate of flux decline from pore blockage.^[381] Compared to other methods of fabricating 3DOMs, including non-solvent-induced phase separation of block copolymers and microelectromechanical systems, IOs offer a simple solution of producing a uniform porous membrane without the need for highly specialized machinery for patterning or fine-tuning the stochastic porous structures for block copolymers.

IO membranes prepared from photoinitiated polymerization of monomer solutions of hydroxybutyl methacrylate and 2-hydroxyethyl methacrylate at differing ratios were demonstrated to be capable of particle fractionation of silica particles in a feed solution.^[378] For samples prepared from 835 nm silica templates, smaller interconnecting pore windows of about 200 nm in the IO membrane prevented larger particles (440 and 835 nm silica particles) from transmitting across the membrane while allowing smaller 60 nm silica particles to pass through. Many battery systems often contain a separator membrane in the electrolyte between the anode and the cathode to prevent electrical contact between the electrodes and maintain ionic flow. Uniform IO structures fabricated from UV curing of ethoxylated trimethylolpropane triacrylate (ETPTA) polymer in a SiO₂ nanoparticle matrix have shown promising applications as battery separator membranes relative to commercial trilayer polypropylene /polyethylene /polypropylene (PP/PE/PP) separators with randomly distributed pores.^[382] In a LiCoO₂ cathode and graphite anode battery configuration, the ETPTA IO separator membranes showed similar performances to the commercial separators at low mass loadings and slow cycling rates and improved performances for high mass loadings and fast cycling rates, as seen in Figure 26a. The improvement in performance was attributed to the increased ion transport through the wellordered, nanoporous structure of the IO separator membrane.

Modifications to macroporous 3DOMs have allowed IO membranes to modify their particle selectivity. Particle-nested IO structures, consisting of polystyrene particles embedded in a poly(urethane acrylate) IO matrix, have been shown to pos-

sess excellent separation efficiency of nanoparticles with the potential to tune the size selectivity of the particle separation via alteration of the size ratio between the nested polystyrene particle and the IO pore window.[383] Nanoparticle separation is attributed to nanochannels formed between the nested polystyrene particle and the IO walls; Au nanoparticles exhibited high rejection rates when the estimated size of the nanochannels was smaller than the Au nanoparticle sizes, as seen in Figure 26b. A hybrid structure combining the macroporous nature of a poly(urethane acrylate) IO matrix with mesoporous block-copolymer (polystyrene-block-polymethyl methacrylate) structures inside the interconnecting pore windows has demonstrated a size-selective nanoparticle separation without comprising the high permeability of the IO structure.^[384] 18 nm nanosieves in the block-copolymer material of the hybrid membrane structure displayed excellent size selectivity in filtering Au nanoparticles with sizes above 18 nm showing complete separation, as seen Figure 26c.

The interconnectivity and increased surface area exposed in 3DOMs has attracted attention for catalytic applications where catalytic reactions are increased due to the macroporous nature of the structured material. Ceria-zirconia IOs ($Ce_{0.5}Zr_{0.5}O_2$) were investigated in relation to the role of the macroporous interconnected geometry of the 3DOM in relation to the catalytic oxidation of propane and compared to $Ce_{0.5}Zr_{0.5}O_2$ catalysts produced from crushed IOs or featuring no template.^[385] The macroporous IO structures featured the best performances, attributed to the increased tortuosity of the gas transport path in the other structures investigated, as seen in **Figure 27**a.

The ordered IO structure can also function as an excellent catalyst support for loading of metal particles onto a semiconductor surface. The high surface area and porosity of an SnO₂ IO were utilized for functionalization of the IO material with monodispersed immobilized Pd nanoparticles which were well dispersed throughout the structure and easily removed postreaction.^[386] Compared to commercially available Pd/C structures, the Pd/SnO₂ IOs demonstrated formic acid oxidation with an onset voltage ~180 mV below the commercial standard, as depicted in Figure 27b. This enhancement effect was attributed to the uniform distribution of particles and the porosity of the IO structure facilitating increased access to catalytically active sites. Some recent works choose to adopt IO structured materials primarily for their ability to easily increase the specific surface available through their natural porosity, thus increasing the number of active catalytic sites for the photocatalyst material.^[387,388] Other works choose IO materials for their ability to easily accommodate metal particles onto a semiconductor

surface due to the open network of material alongside the intrinsic structural porosity, such as noble metal decoration onto TiO₂^[389,390] and ZnO^[235,391] photocatalysts. Double inverse opal structures have also been proposed as a method to confine particulate photocatalysts to a structure without decreasing the active surface area.^[392] From examples in the literature, photocatalysts are frequently structured as 3DOMs, both for the structural advantages of the macroporous structure and optical phenomena such as the slow photon effect, see Section 3 for more details.

IO 3DOMs have seen widespread use in battery electrode research in recent years with the macroporosity of the interconnected electrode being investigated for lightweight, high cycling rate, and high energy density applications. A vast array of different material candidates have been structured with an IO geometry for evaluation of the electrochemical performance as an anode or cathode. On the anode side silicon,^[393] carbon,^[394] germanium,^[395] TiO₂,^[119] GeO₂^[396] and Co₃O₄,^[397] are among some of the materials for which the incorporation of the IO structure has been investigated. IO structures of LiFePO₄,^[398] V₂O₅,^[399,400] and sulfur^[401] (encapsulated by a polypyrrole IO framework) have been explored as cathodes. From the earliest application of a 3DOM to an electrode,^[402] the electrochemical benefits of an IO structure were proposed as a reduction

in electrode polarization compared to bulk materials where mass transport is inhibited by the high tortuosity of ion diffusion paths. Lithium-ion battery electrodes with a 3D structure are thought to reduce the overall cell resistance by improving the electrolyte transport, creating a fast charging capability and reducing the risk of lithium plating in the cell.^[403] For IOs, the macroporous structure facilitates electrolyte access to the electrode material at interstitial points. The IO material walls are also nominally thin relative to the IO pore size, often just several nanometers thick, allowing for short ion diffusion paths and creating high rate capabilities.

In terms of the specific energy associated with an electrode, the specific capacities (capacity per mass of material) for a range of different electrode designs in lithium-ion batteries have been investigated relative to IO designs. For flexible TiO₂ electrodes deposited on carbon cloth, two anatase TiO₂ IO electrodes (3T-CC—annealed in air and 3T-C-CC—annealed in Ar) were investigated versus an anatase TiO₂ nanoparticle slurry on carbon cloth (NP-CC) with carbon black and polyvinylidene difluoride additives.^[404] **Figure 28**a displays the performance of the electrodes compared at a high cycling rate of 10 C with the superior performance of the IO materials displaying larger specific capacities compared to the nanoparticle coating; a larger surface area in contact with the electrolyte and fast

lithiation kinetics were proposed for the superior IO 3DOM performance. A separate study of rutile $TiO_2 IOs^{[119]}$ found that the IO electrode composition was maintained alongside a stable specific capacity across 5000 cycles indicating long-term structural stability and cycle life, even when tested at high cycling rates.

At low cycling rates (<1 C) electrodeposited V₂O₅ cathodes, structured with and without an IO architecture, were found to boost improved specific capacities relative to bulk V₂O₅ films, as seen in Figure 28b.^[399] The V₂O₅ IO cathodes were also found to maintain a dominant intercalation mode response at higher scan rates. The performance of a conversion mode

 Co_3O_4 anode was compared for a 400 nm IO structure and an electrode formed from 400 nm Co₃O₄ microparticles, both deposited on stainless steel.^[397] The ordered IO structure offered significantly higher specific capacity compared to the disordered collection of microparticles, as seen in Figure 28c. Outside of lithium-ion batteries, sodium-ion batteries have also explored the IO structure for their electrodes.^[405–407] amorphous TiO₂ IO architectures, prepared as hollow spheres using atomic layer deposition, were explored for use in sodium-ion batteries and compared to amorphous disordered TiO₂ and planar TiO₂ films.^[405] The ordered IO architecture featured the largest specific capacity and highest rate performance, as depicted in Figure 28d, which was attributed to good electrolyte wettability enhancing the effective surface ion availability, an important consideration in sodium-ion batteries due to the larger ion size relative to lithium-ion batteries.

ADVANCED SCIENCE NEWS _____ www.advancedsciencenews.com

The interconnected electrode material may also achieve better electrical conductivity compared to other material designs aimed at improving surface area interactions. In comparison to interconnected 3DOMs, energy densities in composite nanoparticle coatings are often limited by the requirement of additional binder and conducting agents to ensure electronic conductivity between particles despite the higher relative surface areas nanoparticle electrodes could provide.^[408] As mentioned previously, the porous IO network allows for greater electrolyte access and easier ion insertion/removal. A common observation with IO electrode materials is an impressive C-rate for the battery material; high specific currents are often shown to be fully reversible while maintaining an impressive specific capacity for the system, an important consideration for high energy applications. The macroporosity of the IO structure has also been proposed to help reduce structural stresses in materials with large volume changes during lithium insertion and removal.^[393] Some of these features of IO electrodes are examined in Figure 29.

Figure 29a shows a germanium(IV) dioxide (GeO₂) inverse opal explored as an anode candidate in a lithium-ion battery.^[396] The highly interconnected IO structure of the electrode does not require additional binders or conducting additives and delivers a high specific capacity of 531 mA h g⁻¹ even after 1000 cycles at a specific current of 300 mA g⁻¹. Excellent rate capabilities are also demonstrated with fully reversible cycling present for higher specific currents up to 1000 mA g⁻¹. The potential for asymmetric discharge (1000 mA g⁻¹) and charge (300 mA g⁻¹) rates are also explored. A long-term study for rutile phase TiO₂ IOs is present in Figure 29b, where a TiO₂ IO is investigated as an anode material in lithium-ion batteries for up to 5000 cycles.^[119] The SEM images illustrate that structural stability is maintained in the IO even after long-term cycling. Different specific currents ranging from 75 to 450 mA g⁻¹, approximately yielding C-rates of 0.45 C & 2.68 C respectively, were found to be highly reversible for the material. The IO electrode demonstrated an impressive cycle life, yielding a specific capacity of 95 mA h g^{-1} after 5000 cycles.

Bare carbon inverse opals are compared to mesoporous carbon inverse opals in Figure 29c in relation to their performance as anode materials in lithium-ion batteries.^[409] The extra surface area provided by the mesoporous carbon was thought to establish shorter solid-state diffusion lengths. This

effect, in combination with the inherent high interconnectivity of the IO template, gave larger specific capacities (32% larger after 20 cycles with a specific current of 100 mA g^{-1}) for the mesoporous carbon IO material compared to the bare carbon IO. Composite IO materials consisting of a combination of different active materials have also been explored as electrodes. A SnO₂/GeO₂ composite anode for use in lithium-ion batteries has been explored as a method of mitigating capacity fade from material volume variations commonly experienced in SnO₂ electrodes.^[410] Comparisons in electrochemical performance between bare SnO₂ IOs and composite SnO₂/GeO₂ IOs can be observed in Figure 29d. Most notably, a much higher specific capacity and an improved capacity retention can be observed for the composite IO material. Similar IO works with composite materials of have explored similar strategies to improve the electrochemical performance and stability; Some examples include SnO₂/Bi₂O₃ composite IOs prepared on nickel foam^[412] and Li₂FeSiO₄/C composite nanofibers incorporated into an IO design.^[413] The enhanced rate capabilities and impressive cycle life of IO materials have also been explored for non-lithiumion systems, such as a aqueous zinc-ion battery system with a MnO₂ cathode^[411] shown in Figure 29e. Even after completing 5000 cycles the aqueous system with the layered MnO₂ IO structure shows an impressive specific capacity of 121 mA h g⁻¹ at a high current density of 2000 mA g⁻¹, effects which were attributed to the structure of the cathode.

Conversely, in spite of the relatively large specific energies associated with IO electrodes, the inherently high porosity of the IO structure (26% material, 74% pore space) creates a lower volumetric energy density, when compared to other electrode structures.^[408] Some efforts to enhance the volumetric energy density of IO electrodes have focused on additional material coatings deposited onto the IO scaffold.^[408,414] The inherent high interconnectivity and electrical conductivity, combined with the open porous network, of the materials used in IO electrodes make them ideal candidates for hosting materials within their structure. **Figure 30** explores some examples of how the IO structure has been utilized as a structural template support for other materials and the synergistic performance observed.

A conversion mode IO anode (Ni-Mn-Co-O) consisting of mixed oxides of nickel, manganese, and cobalt used in a lithium-ion battery, both in a half-cell configuration and full cell versus a V_2O_5 cathode, is shown in Figure 30a.^[415] The mixed oxide IO material was further altered via a carbon coating applied to the IO structure with the additional carbon thought to help maintain the structure during cycling. A lithium-sulfur system can be seen in Figure 30b, where the sulfur material for the cathode is infiltrated into a hydrogen-reduced TiO₂ IO network acting as a host material to accommodate volume changes and strain during cycling.^[416] The IO network acts to confine the sulfur material to the cathode and the surrounding hydrogen-reduced TiO₂ material prevents diffusion to the anode by binding with the polysulfide material generated, delivering a high specific capacity of 890 mA h g⁻¹ after 200 cycles at a rate of 0.2 C. Similar strategies are used in other lithiumsulfur works with IOs of carbon^[419] and polypyrrole decorated with ZnO nanocrystals^[420] investigated for confinement.

A Ni IO structural template was modified with two successive material coatings in an attempt to improve the volumetric

energy capacity of porous electrode systems, where specific mass performances are often high yet the volume fraction of active material is often low due to high porosity. Figure 30c displays Ni IO coated with TiO_2 material through atomic layer deposition and then further coated with reduced graphene oxide (RGO) through spray coating for an anode in a lithium-ion battery.^[417] High volumetric capacities are obtained for the electrode system which was thought to arise from the synergistic

effects of all active materials. The inner nickel material was stable while highly conductivity and the similar Li-ion intercalation mechanism in TiO_2 and RGO helped to maintain structural integrity. Silicon IOs are often investigated as anode materials for lithium-ion batteries due to the large specific capacities associated with silicon electrodes. Volumetric expansion of silicon when alloying with lithium-ions often necessitates the need for a porous, structural network to account for volume

changes. Figure 30d shows a comparison between a silicon IO (ISi) and a carbon-coated silicon IO (C-ISi).^[418] The carbon material deposited onto the IO displayed provided stronger specific capacity retention and helped to maintain the structure of the IO network after 100 cycles.

7. Conclusions and Outlook on the Role of Photonic Crystal Materials

The significance of PhCs across a multitude of different areas has been discussed with particular emphasis on the optical application of the structure. The repeating lattice of alternating dielectric materials found in a PhC can be designed for 1D, 2D, and 3D structures with plenty of applications incorporating the optical response of these materials. The properties of the photonic bandgap/stopband associated with a PhC are an essential consideration for any optical application of these structures. As such, the desired wavelength position of the photonic bandgap/stopband for a particular application will dictate the size, geometry, and material of the PhC utilized. For creating waveguides using the reflection from a photonic bandgap, such as in hollow core photonic crystal fibers, the highest possible reflectivity from the photonic bandgap is desirable, often utilizing silica fibers with a full photonic bandgap to accomplish this. The degree of reflectivity is also a concern for PhC reflectors used in solar cell designs, yet not the only consideration. The specificity of the reflection from the PhC can be designed for selectively reflecting certain wavelength ranges in tandem thin film silicon solar cells. Likewise, the porosity of the PhC back reflectors utilized in DSSC systems is a crucial consideration for enabling the electrolyte to interact with dye-sensitized molecules on the electrode surface.

Certain applications act to suppress the peak reflection altogether, treating PhC reflection as an undesirable effect, such as in photocatalysis. Photocatalysts structured as 3DOM, reap the structural benefits of increased surface area and porosity for catalytic reaction sites and the optical benefits of the slow photon effect at the photonic band edges for increased light path lengths and photocatalytic reaction rates. However, peak reflections from PhCs in photocatalysts are often suppressed using the regions of strong electronic absorption of the semiconductor PhC to ensure that light which may be used for initiating photocatalysis is not wasted by reflections from the photocatalyst surface. Conversely, for applications involving PhC sensors, well-defined, easily-observable and tunable photonic bandgaps/stopbands are of paramount concern for optically detecting changes in the sensor system. The sensitivity of the peak reflection/ transmission dip to minor changes in the material environment or modifications to the structure is the core function of the PhC sensor. The key point illustrated from the many successful examples of implementation from the literature is that the strength of the PhC structure is inherently tied to the flexibility of its signature optical response. Depending on the application, the photonic bandgap can be maximized for reflection, suppressed and tuned for slow photon effects or monitored for material changes simply by control over the dimensions of the repeating structure.

Beyond optical applications, the ordered structure of photonic crystals has attracted attention in certain fields, particularly IO 3DOMs. High surface-to-volume ratios, bi-continuous networks of scaffold material and pores, efficient mass transport and relatively easy functionalization of the material walls have established IO PhCs as prominent 3DOMs for a range of structural applications.^[91,364] The interconnecting scaffold and porous structure of the IO have found applications in tissue engineering, selectively porous membranes, catalysis, and battery electrode architectures. Certain areas, such as photocatalysis, have already begun to capitalize on the structural and optical benefits offered by IO PhCs. Slow photon effects can be introduced into the photocatalyst material via tuning of the optical properties of the IO, while exploiting the structural porosity for increased surface area or incorporation of dye molecules and metal particles. There are numerous examples of IO materials being utilized as photocatalysts to capitalize on synergistic effects between the slow photon effect of the IO structure and existing semiconductor modifications e.g., dye-sensitization and plasmonic nanoparticle resonances. The slow photon optical activity of the IO structure is used to improve the performance of the semiconductor material.

Moving forward, the potential of PhCs will most likely be realized from identifying areas where the inclusion of an ordered architecture with a signature optical response can enhance or add functionality to existing technologies. Recently, in situ and operando analysis techniques are a prime example of an emerging application involving IO structures. Structuring existing successful materials as an IO has provided an opportunity to obtain real-time data using a variety of different techniques. When Cu-In alloys used in the electrochemical reduction of CO2 adopted an IO structure, the Cu-In IO displayed efficient CO2 reduction while also allowing a sensitive detection of the CO₂ reduction intermediates using surface-enhanced Raman scattering.^[421] The inclusion of the IO structure dramatically enhanced the Raman signal of the Cu-In alloy when compared to a structure without an IO design, enabling in-situ Raman analysis due to the enhanced signal. This effect is thought to be facilitated by an electric field enhancement where the high curvature of the IO structure concentrates the electric field creating "hot edges." A nickel IO used as a structural scaffold for silicon material has demonstrated a capability of operando identification of strain in an anode used for a lithium-ion battery.^[422] Silicon is known to experience a volume expansion upon lithiation; on an IO architecture, the silicon is free to expand into the IO pores but constrained from expanding into the nickel scaffold, creating a compression on the Ni material. Operando X-ray diffraction monitoring of the strain on the Ni scaffold during lithiation was accomplished using diffraction peak position and peak broadness with the possible identification of amorphous silicon delamination from the scaffold. A similar $study^{\left[423\right] }$ has since adapted this in situ strain measurement technique for Ni₃Sn₂-coated Ni IO anodes.

PhC optical sensors have long demonstrated their capability of acting as in situ monitors on merit of the sensitivity of the photonic bandgap/stopband. Several of these sensing applications have been highlighted throughout this review. PhC sensors have been developed for identification of solvents,^[125,137]

Figure A1. Schematic diagram showing diffraction from crystal planes in photonic crystal structures as per the Bragg-Snell relation.

vapors,^[153] oils,^[148] ions,^[163] biomolecules^[162,166] and nerve agents^[165] to name just a few. The photonic bandgap of the PhC material defines the sensing response of the structure with systems calibrated to interpret changes to the photonic bandgap position to changes in concentration or structure. Extending this optical sensing ability to incorporate into other functional materials has the potential to establish operando monitoring for different techniques. Recently, a reduced oxide graphene film deposited on the surface of an IO acetylcellulose structure displayed a dual functionality for in situ monitoring.^[424] The electrical resistance of the graphene sheet displayed a sensitivity to the tensile/compressive strain applied, allowing human motion to be tracked in situ via changes in resistance. The IO component of the composite sensor allowed NaCl concentrations to be tracked as function of peak reflection position, with the potential to act as a glucose sensor.

Certainly, the work summarized here acts to further extend the sensing applications of PhC materials in the energy storage field using the optics from solid-state physics, and knowledge of advances in photoelectrochemistry and related fields. Lithium-ion battery electrodes are now being designed in the form of an IO PhC with reasonably good electrochemical behavior in battery cells, with the added function of an optical sensor arising from the electrode architecture. The presence of an observable photonic stopband allows an operando monitoring of the electrode during battery operation. For lithium-ion batteries, operando characterization techniques are desirable for the advancing the development of electrode materials due to their potential to provide in-depth information on reaction processes, degradation mechanisms, side reactions, structural evolution, SEI formation, and redox mechanisms.[425,426] X-ray diffraction, microscopy techniques, neutron analysis, scanning probe microscopy, Raman and FTIR spectroscopy are among some of the techniques currently utilized for operando monitoring of lithium-ion batteries. Current research shows ongoing efforts to improve the quality, scale, and design of photonic crystal films through mixed oxide precursors,^[136] precursor coassembly with crystalline nanoparticles,[427,244] increased film wettability during assembly,^[428] particle-nested double inverse opal structures^[392,429,430] and photonic crystal heterostructures with varying lattice size^[134,431,432] or material composition.^[239,433,434] These various strategies show a concerted effort to achieve large-scale crack-free IO photonic crystal films with a strong optical signature. This focus on higher quality films, often with simplified fabrication procedures, should only act to expand the prevalence of IO photonic crystal films in other research areas, particularly in areas which may benefit from an added optical sensor function in addition to the ordered porous network of material present.

Appendix I

Here, the Bragg-Snell model for light diffraction will be derived for the maximum wavelength of destructive interference for light transmission through photonic crystal structures which is indicative of the photonic bandgap position. The condition for maximum constructive interference in the reflected wave is shown, as this corresponds to maximum destructive interference in the transmitted wave. **Figure A1** displays a geometric diagram showing the diffraction angles involved in constructive interference for reflected light waves incident from a medium of refractive index n_1 at some angle θ_1 into a photonic crystal medium of composite refractive index n_{eff} (individual particles of refractive index n_2) with an interplanar spacing *d* between the photonic crystal planes.

With reference to Figure A1, two reflected waves (red and blue arrows) from the photonic crystal surface will be in phase and interfere constructively if the path difference of the refracted wave through the medium is an integer number of wavelengths. The path difference created by refraction is labeled x and the light wave travels this distance twice. For some integer m at a wavelength λ' , the condition for constructive interference in the reflected wave, as per thin film interference, is then:

$$m\lambda' = 2x$$

(A1)

MATERIALS TECHNOLOGIES

www.advmattechnol.de

The path difference x can be found by taking the cosine of the refracted angle as:

SCIENCE NEWS _____ www.advancedsciencenews.com

$$x = d\cos\theta_2 \tag{A2}$$

It is very common to see the refractive index of the photonic crystal medium represented by n_{eff} or n_{avg} , indicating the dependence of the refractive index in the photonic crystal region as some combination of refractive indices of the constituent materials (photonic crystal material + interstitial void space filling). There are different approaches used to estimate the effective refractive index for a photonic crystal medium in the literature. Two of the more common methods used to calculate this parameter for a two material photonic crystal medium (material 1 with refractive index n_1 and volume fraction φ_1 and material 2 with refractive index n_2 and volume fraction φ_2) are given by the models:

$$n_{\rm eff} = n_1 \varphi_1 + n_2 \varphi_2 \tag{A3}$$

$$n_{\rm eff} = \sqrt{n_1^2 \varphi_1 + n_2^2 \varphi_2}$$
 (A4)

Unfortunately, there appears to be an unclear consensus on which method is most suitable for estimating $n_{\rm eff}$ for a given system. Here for simplicity, a general $n_{\rm eff}$ term will be used to derive the final form of the Bragg-Snell equation.

The wavelength λ' corresponds to the wavelength of light in the photonic crystal medium as it passes through a refractive index n_{eff} . This can be related to the vacuum wavelength of light λ exterior to the photonic crystal medium with:

$$\lambda' = \frac{\lambda}{n_{\rm eff}} \tag{A5}$$

Substituting equations (A2) and (A6) back into equation (A1) yields:

$$\frac{m\lambda}{n_{\rm eff}} = 2d\cos\theta_2 \tag{A6}$$

This can also be written as:

$$m\lambda = 2dn_{\rm eff}\cos\theta_2\tag{A7}$$

This can be further modified using Snell's law to create a dependence on θ_1 , which is more easily measured/controlled than θ_2 , with Snell's law giving:

$$\sin\theta_2 = \frac{n_1}{n_{\rm eff}} \sin\theta_1 \tag{A8}$$

Squaring both sides of the equation and subtracting them from 1 allows Equation (A8) to be rewritten as:

$$1 - \sin^2 \theta_2 = 1 - \frac{n_1^2}{n_{\text{eff}}^2} \sin^2 \theta_1$$
 (A9)

Recognizing the left-hand side of Equation (A9) as being equivalent to $\cos^2 \theta_2$, we now have:

 $\cos\theta_2 = \sqrt{1 - \frac{n_1^2}{n_{\text{eff}}^2} \sin^2\theta_1}$ (A10)

Equation (A10) is often further simplified as:

$$\cos\theta_2 = \frac{1}{n_{\rm eff}} \sqrt{n_{\rm eff}^2 - n_1^2 \sin^2 \theta_1} \tag{A11}$$

Substitution of this form of $\cos \theta_2$ into Equation (A7) creates a constructive interference condition for reflected light as:

$$m\lambda = 2d\sqrt{n_{\rm eff}^2 - n_1^2 \sin^2 \theta_1} \tag{A12}$$

Equation (A12) is a general form for the maximum reflected constructive interference wavelength in photonic crystal structures which depends on interplanar spacing *d*, composite refractive index in the photonic crystal medium n_{eff} , refractive index of the surrounding medium n_1 and the angle of incidence for light entering the structure. For opal and inverse opal structures the interplanar spacing of the (111) reflection, the most prominent reflection at normal incidence, using the unit cell parameter can be found as:

$$d_{\rm hkl} = \frac{a}{\sqrt{h^2 + k^2 + l^2}}$$
(A13)

$$d_{111} = \frac{\sqrt{2}D}{\sqrt{3}}$$
 (A14)

The parameter *D* represents the center-to-center distance between adjacent spheres/IO pores for photonic crystal structures. For reflections from the (111) plane in FCC structured photonic crystals the condition for constructive interference can be written as:

$$m\lambda = \sqrt{\frac{8}{3}}D\sqrt{n_{\rm eff}^2 - n_1^2\sin^2\theta_1}$$
(A15)

This form of the constructive interference condition is often presented when working with photonic crystal structures. If the photonic crystal is placed in an air medium ($n_1 = 1$) and a firstorder resonance (m = 1) is being measured, this equation can also be seen represented as:

$$\lambda = 1.633D\sqrt{n_{\rm eff}^2 - \sin^2\theta_1} \tag{A16}$$

Alex Lonergan completed his B.Sc. in Chemical Physics in 2016 at University College Cork, Ireland in 2016, receiving a Graduate of the Year award from the College of Science, Engineering and Food Science. In 2021, he was awarded a Ph.D. in Chemistry from University College under the supervision of Prof. Colm O' Dwyer. Since 2021, he has been working as a postdoctoral researcher in the Applied Nanoscience Group, led by Prof. Colm O' Dwyer. His research is focused on photonic crystal materials and developing innovative ways to incorporate their optical properties into electrochemical processes.

Colm O'Dwyer completed his B.Sc. and Ph.D. in Applied Physics in 1999 and 2003, respectively, at the University of Limerick, Ireland. He conducted postdoctoral research in nanolithography using magneto-optically trapped atom beams at the Université Paul Sabatier, Toulouse, France followed by research on nanostructures for nanoelectronics at Tyndall National Institute. From 2008 to 2012, he was a SFI Stokes Lecturer at the University of Limerick. He is currently professor of Chemical Energy at the University College Cork, leading a group working on electrochemical and optical materials science. He is a fellow of the Institute of Physics and serves as vice-president of The Electrochemical Society (ECS).
