11 Abstract

12 Wave farm planning in a coastal region should lead to the selection of: i) the type of 13 technology of wave energy converter (WEC) providing the highest performance at 14 specific sites and ii) the sites for wave farm operation allowing an integrated coastal 15 zone management (ICZM). On these bases, the deployment of a wave farm should be 16 based on an accurate analysis of the performance of different WECs at coastal locations 17 where wave energy exploitation does not interfere with other coastal uses, and the 18 environmental impact is minimized (or positive, e.g. allowing coastal protection). With 19 this in view, in this piece of research the intra-annual performance of various WECs of 20 the same type (buoy-type) is computed at different locations in NW Spain allowing an ICZM perspective. For this purpose, the intra-annual version of WEDGE-p[®] (Wave 21 22 Energy Diagram Generator – performance) tool is implemented. The results show that, 23 as opposed to previous analysis on WECs with different principle of operation, the level 24 of performance of buoy-type WECs at specific locations may present strong similarities. 25 In this case, an accurate computation of different performance parameters along with 26 their joint analysis emerge as a prerequisite for an informed decision-making.

28 **1. Introduction**

29 Wave energy exploitation represents a major technological challenge due to the need of 30 wave energy converters (WECs) to operate under harsh conditions [1]. Nevertheless, the 31 intense research developed over the last years has led to an increase in WECs' 32 efficiency and a better response under extreme conditions. As a result, a large number 33 of different WECs are currently available, which may be classified based on three 34 aspects: i) distance to the coast, ii) shape and direction and iii) mode of operation [2]. 35 The latter is usually considered the most relevant aspect, according to which three main 36 technologies are usually defined: overtopping devices (OTDs) [3,4], oscillating water 37 columns [5-7] (OWCs), and wave activated bodies (WABs) [8,9]. 38 The most appropriate device for a specific coastal site is function of several aspects. In 39 this context, the magnitude of the resource and its spatial and temporal distribution is of 40 paramount importance. This is caused by their efficiency, which depends on the wave 41 resource characteristics, namely wave height and period. Thus, the device providing the 42 highest performance is site-specific and no general recommendation can be drawn. On 43 these bases, the selection of the most efficient WEC-site combination should be conducted based on a thorough analysis of the performance of several combinations; to 44 45 this end, it has been shown that an exhaustive study on the wave resource distribution 46 following specific procedures is required [10]. In this regard, the wave energy resource 47 may experience significant modifications in short distances caused by the different 48 coastal processes resulting from the interaction of waves with the seabed in their 49 propagation to the coast [11]. In addition, the coastal regions of interest for wave energy 50 exploitation usually exhibit a considerable temporal variability in the resource, with

abrupt seasonal or even monthly variations [12,13], which need to be considered for an
appropriate performance analysis [14].

53 Last but not least, wave energy exploitation represents a new coastal use which has to 54 be considered under an integrated coastal zone management (ICZM) approach [15,16] 55 so as to avoid the interference with other coastal uses along with environmental 56 damage, thereby leading to a sustainable development of the coast [17-19]. With this 57 aim, an ICZM perspective has to be considered for conducting the final decision-58 making when deploying a wave farm in a coastal area (i.e. definition of the most 59 appropriate WEC-site combination). 60 In this piece of research, the intra-annual performance of three WABs of buoy type: 61 Aquabuoy, Bref-HB and F-2HB [20-23], is thoroughly investigated. This specific 62 technology is selected insofar as several wave farms of this type have been proposed 63 over the last years in the Galician region e.g. [24]; however, limited studies on the 64 performance of these devices under real conditions have been conducted. The main 65 characteristics of the selected WECs are shown in Table 1. The performance of these

66 devices is analyzed at different sites within the Galicia coast (NW Spain) (Figure 1)

67 compatible with an ICZM approach.

This study is conducted by implementing the intra-annual version of the recently
patented tool WEDGE-p[®] (Wave Energy Diagram Generator - performance) [25]. The
tool is now available within a brand-new interface allowing the self-contained
computation of the relevant intra-annual performance parameters of WECs at the
locations of interest, which in turn are selected through a Geographical Information
System (GIS) viewer, containing the relevant socioeconomic and environmental spatial
data in the region.

75	
76	[FIGURE 1]
77	[TABLE 1]
78	
79	The paper is structured in five sections. In first place, in Section 2, the data
80	requirements both in terms of wave characterization and from an environmental and
81	socioeconomic standpoint are presented. Then, in Section 3, the procedure followed for
82	implementing the tool in the coastal area of interest is briefly discussed. In Section 4,
83	the performance results are thoroughly presented for the different WEC-site
84	combinations of interest. In Section 5, a comprehensive discussion on the implications
85	of the results presented is conducted. Finally, the main conclusions are established in
86	Section 6.
87	
88	2. Data requirements for wave energy exploitation decision-making
89	The wave data currently available in most of the coastal areas are not sufficient for an
90	appropriate decision-making when deploying a wave farm. This limitation results, in
91	first instance, from how WECs operate. The efficiency is usually given through a
92	power matrix which provides the power output, P, for the different wave conditions

93 usually expressed in terms of significant wave height, H_{m0} , and wave energy period, T_e .

94 In Figure 2 the power matrices of the devices selected are presented. It can be observed

95 that the power output strongly varies depending on the existing conditions, presenting

96 the highest efficiency within an approximately narrow band of H_{m0} in the range of 4-7

97 m, and a wider range of T_e , roughly 6-13 s. These characteristics of the resource will

98	cause a significant variation in the performance attained by the selected WECs at
99	different locations; nevertheless, this variation is not likely to be as abrupt as when
100	comparing devices with different principle of operation, which usually attain the highest
101	efficiency in bands of H_{mo} and T_e greatly differing amongst them.
102	
103	[FIGURE 2]
104	
105	Furthermore, the way in which the efficiency is provided by device developers causes
106	that the wave energy resource should be characterized following specific procedures
107	allowing the computation of the so-called characterization matrices containing the
108	occurrence and total energy provided by the different wave conditions [10]. Therefore,
109	by combining the WEC's power matrix with the characterization matrix at a site of
110	interest with the same level of resolution, the power performance of a specific WEC-site
111	combination is obtained. In this context, the intra-annual figures of the performance
112	need to be analyzed for which the characterization matrices obtained should correspond
113	with the temporal period capable of reflecting the intra-annual variability of the
114	resource.
115	Finally, when selecting the sites for wave energy exploitation at which the
116	aforementioned characterization matrices are computed, as stated, the socioeconomic
117	and environmental aspects should be considered so as to avoid the interference with
118	other coastal uses and environmental damage, thereby leading to an effective ICZM.
119	With this in view, the intra-annual version of the brand new tool WEDGE-p [®] [25],
120	based on complex wave resource characterization methodologies [10] considering high-

121 resolution numerical modelling, instrumental wave data, along with a vast amount of 122 environmental and socioeconomic information, is implemented and used to evaluate the 123 performance of the selected WECs. The tool provides the resource information in the 124 form of monthly characterization matrices with any desired resolution of wave intervals 125 at the coastal sites of interest, from which it automatically computes the performance of 126 any WEC in terms of various parameters (Section 3). In addition, it also incorporates a 127 Geographical Information System (GIS) viewer including the existing coastal uses and 128 environmental data, e.g.: transport routes, fishing and shellfish areas, environmental 129 protected zones, etc. Therefore, by combining the socioeconomic and environmental 130 information with the resource and performance data obtained, an informed decision-131 making can be conducted. In the next section, the principal characteristics of the tool 132 and its implementation to the coastal area of interest are presented.

133

134 **3. Tool development and implementation**

135 **3.1. Intra-annual WEDGE-p**[®] development

136 The procedure followed for developing the present tool is based on the deepwater 137 energy bin concept [26] and its numerical propagation towards the coast. On these 138 bases, the most representative offshore energy bins, i.e., trivariate combinations or 139 intervals of significant wave height, H_{m0} , energy period, T_e and wave direction, θ_m , with 140 a specific resolution, are selected and propagated towards the coastal area of interest. 141 The energy bins considered are obtained from the nearest offshore buoy, representative 142 of the surrounding deepwater area, by analyzing a 122712 hourly sea states recorded 143 over a total of 15 years. The resolution of energy bins is established at 0.5 m of H_{m0} , 0.5 144 s of T_e and 22.5 of θ_m . Then, the most energetic bins providing 95% of the total energy available are retained, representing almost 100% of the exploitable resource [27]. 145 146 Next, the offshore energy bins retained are propagated towards the coast through high-147 resolution spectral numerical modelling. More specifically, the SWAN (Simulating 148 WAves Nearhore) model is implemented, being commonly used in wave resource 149 assessments [28-32]. In particular, the model has been previously implemented to this 150 coastal region and successfully validated against field data [27,33]. The model is capable of accurately computing the different wave transformation processes by solving 151 152 the action balance equation given by:

153
$$\frac{\partial}{\partial t}N + \nabla \cdot (\vec{C}N) + \frac{\partial}{\partial \theta}(C_{\theta}N) + \frac{\partial}{\partial \sigma}(C_{\sigma}N) = \frac{S_{t}}{\sigma}$$
(1)

154 where *N* stands for the wave action density, *t* is the time, *C* represents the propagation 155 velocity in the geographical space, θ and σ are the direction of the waves and the 156 relative frequency, respectively, C_{θ} and C_{σ} represent the propagation velocities in the θ -157 and σ - space, respectively, and finally, *S* is the source term given by:

158
$$S_t = S_{in} + S_{nl3} + S_{nl4} + S_{wc} + S_f + S_{br}$$
 (2)

where S_{in} represents the generation by wind, S_{nl3} y S_{nl4} stand for triad and quadruplet wave-wave interactions, respectively, and finally S_{wc} , S_f , S_{br} account for dissipation due to whitecapping, bottom friction and wave breaking, respectively [34]. The area covered by the numerical model grid and its bathymetric configuration is presented in Figure 3. As a result of the numerical propagations a reduced number of energy bins are obtained at each node of the numerical grid, i.e., at each location with a given spatial resolution. In other words, at each coastal site a number of wave conditions with a given

166	occurrence are made available. In the present case, the occurrence is computed in terms
167	of monthly figures, and thus this information can be used to reconstruct high-resolution
168	monthly characterization matrices at the sites of interest.
169	
170	[FIGURE 3]
171	
172	Finally, by combining the resource information contained in the characterization
173	matrices with the efficiency provided by the power matrix of a given WEC, the
174	performance of a specific WEC-site combination is obtained. This is automatically
175	computed by the tool as follows. First, the total energy production of a WEC-site
176	combination, E_0 , is obtained by combining each WEC's power output as provided by
177	the power matrix, P_i , with its corresponding occurrence, $O_{b,i}$, in the characterization
178	matrix of the site, i.e.:
179	$E_0 = \sum_{i=1}^n P_i O_{b,i} \tag{3}$
180	where n is the total number of energy bins considered. Given that the energy production
181	may greatly differ amongst devices stemming from their different rated power, P_r
182	(Table 1), the computation of further parameters is required to an accurate analysis of
183	the WECs' behavior. In this way, the capacity factor, C_f , is also computed by the tool
184	as:

$$185 C_f = \frac{E_0}{P_r h} \times 100 (4)$$

Finally, in order to have the full picture of the hydrodynamic performance of the WECsite combinations selected, the capture width, *CW*, and capture width ratio, *CWR*, [20] are also computed. *CW* is given by:

$$189 \qquad CW = \frac{P}{J} \tag{5}$$

190 where P(W) is the output power and J the total available power. CWR is obtained as:

$$191 \qquad CWR = \frac{P}{JB} \times 100 \tag{6}$$

where *B* is the characteristic dimension of the WEC [21,22]. The relevant information
for its computation along with the resulting values are presented in Table 2. The
aforementioned parameters are automatically determined by WEDGE-p[®] tool, for
which the WECs' power matrices currently provided by device developers are
incorporated within it. For a more detailed description of the procedure on which this
tool is based, the reader is referred to previous research into its development [25,35].

198

199

200

201 **3.2. Application to a case study**

202 WEDGE-p tool is applied to a specific area within the Death Coast of Galicia (NW

203 Spain), the region with largest potential in the Iberian Peninsula, where a WEC of buoy-

[TABLE 2]

204 type has been recently deployed [24]. For this purpose, first, the socioeconomic and

205 environmental information together with the bathymetric data contained in the tool are

used for selecting three Points: A, B and C with depths 40.2, 72.0 and 99.4 m,

207	respectively (Figure 1). These locations are selected so as to it make possible an ICZM
208	approach within which, on one hand wave energy operation does not interfere with
209	other coastal uses, and on the other hand potential environmental impacts are
210	minimised. In this regard, aspects such as the potential impacts of the operation of a
211	wave farm over the adjacent area —either negative or positive, e.g., its capability for
212	coastal protection [36]— are out of the scope of this work. However, they may be of
213	major interest for an ICZM approach and should be analyzed for each case study
214	following specific procedures [37-39] prior to installing a wave farm.
215	Once defined the locations, their characterization matrices are obtained, both in terms of
216	annual (Figure 4) and intra-annual figures (Figures 5). It can be seen that, despite their
217	being separated by short distances, their resource characteristics present certain
218	differences, as it is apparent by the distribution of energy amongst bins, overall
219	presenting a slight reduction in the total energy available with the reduction of depth.
220	The major part of the energy available is neither provided by extreme sea states nor
221	conditions with low wave height, which in turn are those not retained within 95% of
222	energy level analyzed, and therefore allowing the consideration of virtually 100% of the
223	exploitable resource. Regarding the intra-annual variability in the resource, profound
224	variations in both the distribution of the energy amongst bins and the total energy
225	available are apparent, thereby highlighting the importance of determining the
226	performance during short periods, e.g., in terms of monthly figures. In the next section,
227	the results of the monthly performance for all the WEC-site combinations selected are
228	presented.

[FIGURE 4]

231	[FIGURE 5]
232	
233	4. Monthly performance analysis of WEC-site combinations
234	The monthly performance attained by the selected buoy-type WECs (Aquabuoy, Bref-
235	HB and F-2HB) is computed at the three locations defined for wave energy exploitation
236	allowing an ICZM approach (Section 3.2).
237	In Figures 6, 7 and 8 the intra-annual energy output E_o and capacity factor C_f expressed
238	in terms of monthly figures are plotted at Points A, B and C respectively for the three
239	technologies. Overall, it can be observed that the magnitude of these parameters
240	presents a strong intra-annual variability, along with significant differences amongst the
241	combinations analyzed.
242	
243	[FIGURE 6]
244	[FIGURE 7]
245	[FIGURE 8]
246	
247	At the three locations selected, the greatest E_o is provided by F-2HB, followed by
248	Aquabuoy and Bref-HB. In the same way, the greatest E_o is attained by the three
249	technologies at Point C (Figure 8) with mean annual figures of 105.32, 33.54 and 2.23
250	MWh for F-2HB, Aquabuoy and Bref-HB, respectively, overall showing large
251	differences amongst them in production, of the order of 200% (F-2HB and Aquabuoy)

and 5000% (F-2HB and Bref-HB). In addition, they show a similar intra-annual trend,

253 maintaining the aforementioned positions throughout the year. This pattern can be 254 roughly described by a certain stability in the energy production from January to March 255 with figures clearly higher than the monthly average; then, in April, E_o begins to 256 experience a significantly reduction which is maintained until July and August during 257 which the lowest values are obtained. Then, E_o shows a significant increase during 258 September and October levelling out over the last one quarter of the year. In all the 259 combinations the months with the greatest production are January and February, approx. 260 350-400% higher than that obtained during the months with lowest production, attained 261 in August and closely followed by July.

262 The same general description in the intraannual variability of E_o applies to the capacity 263 factor, C_{f} , as established by Equations 3 and 4; nevertheless, the level of performance of 264 the devices analyzed greatly differs from those drawn for E_o . In this case, the device 265 overall providing the highest performance (annual mean), at the three locations selected 266 is Bref-HB, followed by Aquabuoy and F-2HB, i.e., the reverse order of that obtained 267 for E_o ; however, in contrast to E_o results, their positions are not conserved throughout 268 the year, as it is apparent in the case of Aquabuoy technology attaining the highest 269 performance over the first and last one third of the year. In addition, the differences 270 amongst technologies are now more reduced. At point C, again the site allowing the 271 highest performance, the C_f obtained are 20.39, 18.42 and 14.47%, respectively, with 272 differences amongst devices of roughly 10% (Bref-HB and Aquabuoy) and 20% (Bref-273 HB and F-2HB). This is due to the large disparity in their rated power, which causes 274 that the energy production parameter cannot be solely used to analyze the performance 275 of WECs; in contrast, other parameters such as the equivalent hours, usually considered 276 in wind energy or the capacity factor, as it is the present case, should be computed.

277	However, in order to have the full picture of the performance of the WEC-sites selected,
278	the parameters capture width, CW, and capture width ratio, CWR, are also computed. In
279	Figures 9, 10 and 11, their results are plotted at Points A, B and C, respectively.
280	
281	[FIGURE 9]
282	[FIGURE 10]
283	[FIGURE 11]
284	
285	In the case of CW, the largest mean annual figures are provided, in the same way as in
286	the energy output parameter, by F-2HB followed by Aquabuoy and Bref-HB.
287	Nevertheless, in this case Point C is not that allowing the highest performance for the
288	three technologies; now the greatest values are obtained by F-2HB at location B with a
289	mean annual value of 5.15 m, by Aquabuoy at location B with 1.65 m, and by Bref-HB
290	at location C with 0.13 m, yet similar values are attained at the remaining locations. On
291	the other hand, the marked intra-annual variability previously observed is now much
292	more reduced yet intra-annual variations of up to approx. 200% are still present in the
293	case of Bref-HB. In addition, the intra-annual pattern completely differs from that
294	previously presented; now April and September are the months providing the highest
295	performance in the case of Aquabuoy and F-2HB (although in the latter case, the intra-
296	annual variations are very low), and the summer period in the case of Bref-HB.
297	Despite of the interest of <i>CW</i> parameter, an accurate comparison between the available
298	and output power requires the consideration of the characteristic dimension of the WEC
299	which leads to the definition of capture width ratio, CWR. The greatest figures of CWR

provided by Aquabuoy with 27.44% at Point B, closely followed by F-2HB with 25.77
% at Point C and at a great distance by Bref-HB with 4.20% at Point C, with again very
similar figures amongst locations. Finally, as it could be expected from Eqs. 5 and 6, the
spatial (locations A, B and C) and temporal variations (monthly variations) follows the
same pattern as that depicted in the case of *CW* parameter.

305

306 **5. Discussion**

307 At the three locations selected, the greatest E_{o} in terms of mean annual figures is 308 provided by F-2HB, followed by Aquabuoy and Bref-HB, being attained by the three 309 technologies at Point C, and showing markedly differences in their production of about 310 200-5000%, which is expected to be primarily caused by their rated power and not by 311 their efficiency. However, the different energy distribution amongst bins at the three 312 sites of interest is not reflected in significant differences in the resulting performance. In 313 addition, the selected WECs show a similar intra-annual trend, maintaining the 314 aforementioned positions throughout the year with an intra-annual variation in E_0 of 315 about 350-400%.

The large disparity in the rated power causes E_o not to be a reliable parameter of energy performance analysis, being utterly necessary to compute other parameters such as the capacity factor, C_f . The results obtained show that this parameter, as it could expected, presents a similar trend in terms of intra-annual variability; however, and in contrast to E_o , the performance attained by the selected WECs is relatively similar, being Bref-HB the device with overall the highest performance (which corresponds to the device with

322 lowest E_0), followed by Aquabuoy and F-2HB with differences of about 10-20%, and 323 not maintaining their positions throughout the year.

324 The previous parameters depict the most important aspects of the performance of the 325 WEC-site combinations selected. Nevertheless, they do not accurately reflect their 326 hydrodynamic performance. With this in view, the capture width, CW, and capture 327 width ratio, CWR, are also computed. In the case of CW, the highest performance is 328 attained, as in the case of the energy output, by F-2HB, followed by Aquabuoy and 329 Bref-HB. In addition, as in the case of the previous parameters, the different distribution 330 of the resource amongst energy bins does not result in significant variations in the 331 performance at the different locations of interest. Regarding the intra-annual variability 332 pattern, it differs from that provided by the previous parameters; now, only strong intra-333 annual variations are apparent in the case of Bref-HB, which in addition presents the 334 greatest values during summer months, in contrast with the results previously presented. 335 This results from the variation in the output power being compensated by the reduction 336 in the total available power, indicating that the these WECs maintain an appropriate 337 level of performance over a wide range of conditions. Finally, from the analysis of CWR 338 results, further information emerges. Now, Aquabuoy presents the greatest values, 339 closely followed by F2HB, while the performance of Bref-HB plummets. The low 340 performance attained by Bref-HB —which provides the highest capacity factor— is due 341 to its low surface (perpendicular to wave direction) available for harnessing wave 342 energy in comparison with the other two technologies. These results clearly indicates 343 that despite of the great interest of CW and CWR parameters, the latter being considered 344 as that reflecting more accurately the hydrodynamic performance of WECs, other 345 parameters such as the capacity factor are required for an appropriate analysis of WECs'

performance, in particular for describing the intra-annual variability in the energy
production, and for considering other geometric characteristics (in addition to the
characteristic diameter) which can be of interest.

349 On the other hand, it is important to highlight that the results obtained differ to some 350 extent from previous analysis on the performance of WECs at different locations within 351 the same coastal region e.g., [14]. When comparing devices with different principle of 352 operation, the variation in the performance amongst them is usually shown to be larger 353 than in the present case. This is due to the fact that each technology is more adapted to 354 operate in a specific range of wave conditions and therefore the performance is much 355 more sensitive to the resource characteristics at the location selected. In fact, in this 356 case, it can occur that a specific technology provides the highest performance at a given 357 location, while at a close location the greatest figures are attained by other technology 358 [14]. This is not the case of the present study, which is probably the result —in addition to the similarities in the resource characteristics at the locations selected— of analysing 359 360 WECs with the same principle of operation (buoy-type technologies).

361

362 **6.** Conclusions

In this paper, the intra-annual performance of various buoy-type WECs is computed and analyzed at different coastal locations based on an ICZM approach. For this purpose, the intra-annual version of WEDGE-p[®] tool is implemented to this region, which is developed by using complex procedures considering numerical modelling and an extensive set of instrumental data. As a result, the tool made available contains a large set of new data allowing the self-contained computation of high-resolution 369 characterization matrices and on their bases different performance parameter of any 370 WEC of interest. In addition, the tool incorporates a GIS viewer with the different 371 coastal uses within the region of interest, along with the areas of environmental interest, 372 which should be combined with the aforementioned wave data so as to lead to a 373 sustainable development of the coast when introducing a new use, as it is the case of 374 wave energy exploitation.

The tool is used to select three locations from an integrated coastal management perspective, i.e., where wave farm operation does not interfere with other coastal uses and the environmental impact is expected to be minimum. Then, the characterization of the resource is obtained, and on their bases the intra-annual performance of three WECs with the same type of technology (buoy-type WAB), Aquabuoy, Bref-HB and F-2HB, is determined in terms of energy output, capacity factor, capture width and capture width ratio.

382 The results show that the performance largely differs depending on the parameter 383 analyzed. Amongst all of them, the capacity factor and capture width ratio emerge as 384 the most important parameters, capable of both capturing the intra-annual variability in 385 the performance along with reliable figures of the hydrodynamic performance. The 386 disparity in the results obtained highlight the need for considering both parameters so as 387 to appropriately describe the performance of WECs at specific locations, along with 388 accurately reflecting the intra-annual variability in the production and avoiding 389 misleading results arising from considerations regarding the geometric configuration or 390 the rated power.

On the other hand, the results presented in this research differ from those provided byprevious works dealing with the performance of WECs with different principle of

393 operation, in which the differences in their performance have shown to be larger than in 394 the present study. This is due, to a certain extent, to the fact that each type technology is 395 likely to be more adapted to operate in a specific range of wave conditions and therefore 396 the performance varies more abruptly with the location selected. Therefore, and given 397 the results obtained in the present study, the selection of the most appropriate WEC-site 398 combination proposed in this work requires an exhaustive cost analysis, which is out of 399 the scope of this work.

400 All in all, the results show the importance of implementing specific procedures for wave

401 resource analysis allowing the accurate computation of different intra-annual

402 performance parameters leading to an informed decision-making when installing a wave

403 farm in a region. At the present time WEDGE-p[®] tool is only available for the Galician

404 coast; however, it could be developed and implemented to any other coastal region

405 where long-term offshore wave data are available. In future work, the tool is expected to

406 be extended throughout the Atlantic Region of Europe.

407

408 Acknowledgements

WEDGE-p[®] tool is the result of an extensive work developed in the framework of
several research projects supported by the Ministry of Science and Innovation: *Evaluación de los Recursos Energéticos Renovables* (Ref. DPI2009-14546-CO2-02),
Xunta de Galicia: Consolidación e estruturación – 2016 CIGEO (Ref ED431B
2019/30), Fundación Iberdrola: Online Application and High Resolution Management
System for the Exploitation of the Wave Energy Resource in the Atlantic Region of
Europe, and Fundación Barrié: Development of a Geospatial Database for the

416 Exploitation of the Wave Energy Resource along the Galician Coast. During this work 417 I. López was supported by the postdoctoral grant ED481B 2016/125-0 of the 'Programa de Axudas á etapa posdoutoral da Xunta de Galicia'. The authors are grateful to Puertos 418 419 del Estado for providing the wave data, and to Instituto Español de Oceanográfía (IEO) and Instituto Técnolóxico para o Control do Medio Mariño de Galicia (Intecmar) for the 420 421 ocean uses and environmental data.
