18   **Abstract**

19   Patterned films are essential to the commonplace technologies of modern life. However, they

20   come at high cost to the planet, being produced from non-renewable, petrochemical-derived

21   polymers and utilising substrates that require harsh, top-down etching techniques.

22   Biopolymers offer a cheap, sustainable and viable alternative easily integrated into existing

23   production techniques. We describe a simple method for the production of patterned

24   biopolymer surfaces and the assignment of each biopolymer domain, which allows for selective

1

metal incorporation used in many patterning applications. Protein and polysaccharide domains were identified by selective etching and metal incorporation; a first for biopolymer blends. Morphologies akin to those observed with synthetic polymer blends and block-copolymers were realised across a large range of feature diameter (200 nm to - 20 μm) and types (salami structure, continuous, porous and droplet-matrix). The morphologies of the films were tuneable with simple recipe changes, highlighting that these biopolymer blends are a feasible alternative to traditional polymers when patterning surfaces. The protein to polysaccharide ratio, viscosity, casting method and spin speed were found to influence the final film morphology. High protein concentrations generally resulted in porous structures whereas higher polysaccharide concentrations resulted in spherical discontinuous domains. Low spin speed conditions resulted in growth of protuberances ranging from 200 nm to 22 μm in diameter, while higher spin speeds resulted in more monodisperse features, with smaller maximal diameter structures ranging from 300 nm to 12.5 μm.

Introduction

There is an urgent and growing need for micro- and nano-structured surfaces that can be produced at low environmental and economic cost. Micro- and nano-structured surfaces are essential to an array of advanced and emerging technologies. In 2016 the OECD identified 40 key emerging technologies for the future, including the "internet of things" smart devices, light technologies, regenerative medicine and tissue engineering, nanomaterials, nanodevices, carbon nanotubes, functional materials, synthetic biology, and marine and tidal power technologies. One fifth of these require patterned thin-films as integral components or as essential aspects of their production processes [1].

49   Micro- and nano-structured surfaces occur throughout the natural world and exhibit a

50   range of useful properties; self-cleaning and hydrophobicity (lotus leaf)[2]; anti-reflectivity

51   (moth eyes)[3]; iridescence (butterfly wings)[3]; anti-ice formation (kale) [4]; and anti-fouling

52   (shark skin)[5], to name only a few. Current human manufacturing of equivalent surfaces uses

53   top-down and bottom-up approaches: top-down is expensive, wasteful, not readily scalable,

54   and generally restricted to planar surfaces.[3] Bottom-up requires the use of block co-polymers

55   (BCPs) which can be expensive, are synthetically derived, require environmentally damaging

56   organic solvents and require intricate control of the polymer-surface interface via brush

57   layers.[6] Feature diameter and spacing is limited to sub-100 nm due to the kinetic penalties

58   imposed on high molecular weight BCPs requiring long annealing times, limiting their

59   applications in the optics industry. Additionally, refining BCPs of a high molecular weight to

60   obtain a polydispersity index (PDI) close to 1 is difficult and costly.[3]

61   In contrast, to BCPs and other synthetic polymers, proteins innately have a PDI of 1, are

62   cheap, abundant, renewable, do not require the use of toxic solvents and are easy to

63   manufacture.[7] More generally, biopolymers (proteins and polysaccharides) are well-defined

64   with varied functionality[8], hydrophilic, photostable, nontoxic, biocompatible[9], [10] and

65   have predictable viscosities.[11] The domain sizes of features in polymer blends (synthetic

66   and biopolymer) have been shown to exceed to 10 µm, although feature size showed

67   considerable variance.[12]–[19] For decades biopolymer blends have been utilised in food

68   texturing[15], [16], [19], [20], with few notable examples using biopolymer blends beyond

69   this.[21], [22], [31], [32], [23]–[30] These, however, incorporated synthetic polymer additives,

70   biopolymer derivatives, and/or specialist enzymes for etching or functionalisation of patterned

71   surfaces. This renders these techniques either unsuitable for large scale manufacturing or

72   environmentally damaging. Protein blends are expected to become prevalent in electronic,

73   optical, chemical, mechanical, biomedical and nanotech applications in the coming years.[33]

74   However, the use of biopolymer blend thin films in materials science for surface patterning is

75   further limited by the relative infancy of the field.[31]

76   The aim of this study was the further development of bovine serum albumin (BSA) and

77   chitosan (Ch) blend thin films, using a protic solvent (formic acid, FA) to promote segregative

78   phase separation in a rapid and facile manner. Current efforts to replace BCPs involve the use

79   of synthetic polymer blends to generate patterns. However, as with BCPs, these are not

80   renewable. To offer an alternative, renewable solution to both BCPs and synthetic polymer

81   blends, biopolymer blend thin films must show that they can achieve similar patterns, using

82   established methods. To this end, BSA and Ch were chosen as our biopolymers. BSA and Ch

83   may be blended without fear of gelation when subjected to shear forces.[34] Ch is also

84   antimicrobial[35], biocompatible and biodegradable, increasing the number of possible

85   applications.[36] Finally, both BSA[37] and Ch[38], [39] can selectively bind metals, similar

86   to BCPs. Synthetic polymer blends utilize selective removal of one polymer domain, followed

87   by deposition of a metal to generate a patterned hard mask. In our work, we successfully

88   removed the protein domain using a buffer solution, and selectively incorporated metal into the

89   polysaccharide domain. BSA-Ch blends achieve feature diameters comparable with synthetic

90   polymer blends.[3], [40], [41] This method could be easily employed in other studies of

91   biopolymer blends. Furthermore, this is the first time a hard mask has been produced with

92   bottom-up biopolymer blends. Lastly, we have successfully differentiated the growth

93   mechanisms occurring with dissimilar blend compositions.

94

Experimental

Biopolymers, Casting Solutions and Substrate

Low molecular weight chitosan (Ch, 50-190 kDa, > 75 % deacetylation) and bovine serum albumin (BSA, lyophilised powder, ≥ 96 %, molecular weight ~66 kDa) were purchased from Sigma Aldrich. While the Ch we sourced was the deacetylated form of chitin (i.e. a chitin derivative, which may be considered a semisynthetic), Ch may also be sourced from fungal biomass without the need for derivatization.[42] Ch is renewable, and it is much more easily solubilized than chitin. Hence it was chosen for this work. Low molecular weight chitosan was chosen as it was shown previously shown to be easily solubilized in the FA, while not being excessively viscous.[34] Substrates used in all cases were Fisherbrand™ Microscopic Slides with Ground Edges (plain) or planar substrates. Highly polished single-crystal silicon <100> wafers (p-type, boron) with a native oxide layer of ~2 nm were also used. For FTIR, XPS, water contact angle, and selective metal inclusion, samples were deposited on a Si substrate. This was done to prevent any deformation of a glass substrate during annealing. The solvent used was formic acid (FA), 98+ %, pure (ACROS Organics™) and was diluted to 90 % w/v with distilled water before use. Casting solutions were prepared using 90 % formic acid as the solvent to ensure that the biopolymers were below their isoelectric point in solution and so, positively charged.

Solution Preparation

Biopolymers blend preparation may be found in our previous work, or in our Supporting Information. In short, stock solutions were made by dissolving biopolymers in 90 % FA, and stored at -20 ℃. Before coating, stock solutions mixed with one another and diluted with fresh FA.[34] 5 solutions were prepared. 4 w/v% BSA 1 w/v% Ch (4:1 blend ratio), 2 w/v% BSA

119   1 w/v% Ch (2:1 blend ratio), 1 w/v% BSA 1 w/v% Ch (1:1 blend ratio), 1 w/v% BSA 2 w/v%

120   Ch (1:2 blend ratio) and 1 w/v% BSA 4 w/v% Ch (1:4 blend ratio).

121

122   **Coating Preparation**

123   *Thin-film Casting*

124   Thin-films were prepared using a spin coater (Speciality Coating Systems, 6800 Spin Coater

125   Series) to produce biopolymer solution coatings of uniform thickness. Standard conditions: 30

126   s spin time (ramp time 5 s, dwell 25 s). Substrates were glass slides onto which single

127   biopolymer solutions were cast. Temperature and humidity was maintained at approx. 18 ℃

128   and 65 % relative humidity. Monitoring of humidity and ambient temperature was done by

129   *HOBO MX Temp/RH Logger* sensor.

130

131   *Atomic Force Microscopy (AFM)*

132   Sample morphology was analysed by atomic force microscopy (AFM) using a Park

133   Systems, XE-100 instrument under ambient conditions in non-contact mode, and this

134   methodology was used in our previous work.[34] Scans were performed in non-contact mode

135   with high resolution, silicon micro-cantilever tips. Topographic images were recorded at a

136   resonance frequency of 270-300 kHz. Images were analysed using *Park XEI* and *Gwyddion*,

137   and resulting data analysed using *Origin.* Images were flattened by removal of the background

138   plane (using a first or second regression order). Features were then identified using the

139   Gwyddion watershed algorithm for analysis, and descriptive statistics calculated using

140   "Microcal Origin" software. Surface roughness (nm) and surface area ratios (%) were

141   measured using "XEI" software. RMS (*root means square arithmetical mean roughness* or

142   *root means square average roughness*) is the average between the height deviations and the

143   mean line/surface, taken over the evaluation length/area. Surface area ratios (%) were

144 calculated by the following formula: Surface Area Ratio (%) = 100 (%) × (Geometric Area –

145 Surface Area) / (Geometric Area). Surface feature diameters were measured using the

146 Gwyddion watershed algorithm for scanning probe microscopy (approx. 1000 features). Film

147 thickness was determined by AFM. AFM height scans were performed on areas which had

148 been scratched to expose the underlying substrate.[26]

149

150 *X-Ray photoelectron spectroscopy (XPS)*

151 XPS spectra were acquired on an Oxford Applied Research Escabase XPS system equipped

152 with a CLASS VM 100 mm mean radius hemispherical electron energy analyser with a five-

153 channel detector arrangement in an analysis chamber with a base pressure of 10×10^{-10} mbar.

154 Survey scans were acquired between 0-1000 eV with a step size of 0.7 eV, a dwell time of 0.5

155 s and pass energy of 50 eV. Core level scans were acquired at the applicable binding energy

156 range for each core level, with a step size of 0.1 eV, dwell time of 0.1 s and pass energy of 20

157 eV averaged over 20 scans. A non-monochromated Al-kα x-ray source at 200 W power was

158 used for all scans. Multiplier voltage was maintained at 2.0 kV for all acquisitions. All spectra

159 were acquired at a take-off angle of 90º with respect to the analyser axis and were charge

160 corrected with respect to the C 1s photoelectric line by rigidly shifting the binding energy scale

161 to 285 eV. Data were processed using CasaXPS software where a Shirley background

162 correction was applied and peaks were fitted to Voigt profiles.

163 *Attenuated Total Reflection Fourier Transform Infra-Red (ATR-FTIR) Spectroscopy*

164 Infrared spectra were recorded on a PerkinElmer Spectrum 2 FT-IR Spectrometer. Perkin-

165 Elmer Spectrum v5.0.1 software was used to perform baseline corrections and evaluate spectra.

166 Each spectrum was scanned between 400 and 4000 cm^{-1} with a resolution of 4 cm^{-1} and a

167 minimum of 64 scans were collected and averaged in order to gain good quality spectra.

168

Selective Etching

170 A wet etch was used in order to selectively remove BSA over Ch due to its limited solubility.

171 [43] Biopolymer blend films were crosslinked with a 20 wt% glutaraldehyde solution for 20

172 hr. Coated substrates were immersed in a buffered solution stirring for 20 hr at 300 rpm.

173 Buffered solutions contained 200 mM Tris-HCl, pH 8.8. The substrate was then washed

174 thoroughly with deionised water to remove residual salt. Finally, the substrate was washed

175 with isopropanol alcohol and dried under nitrogen for analysis.

176

Selective metal inclusion

178 To confirm the results of the selective etching of BSA using a basic buffer solution, and identify

179 the Ch domain, selective inclusion of the metal into the Ch domain used. As a 1:1 BSA-Ch

180 blend used to identify the BSA domain using a selective etch, the 1:1 BSA-Ch blend was also

181 used for selective metal inclusion. 1:1 blend films were prepared as described in the Thin-film

182 Casting section, producing a film with discontinuous spheres in a matrix. After casting, films

183 were crosslinked with a 20 wt% glutaraldehyde solution for 20 hr to prevent oversaturation of

184 metals in the Ch domain. 1 wt% $FeCl_3$ solutions were produced with anhydrous ethanol.

185 Biopolymer blend films were covered with 1 ml of metal solution for 15 s before spin coating.

186 The films were then immediately spin coated for 30 s (3000 rpm, ramp time 5 s, dwell 25 s).

187 The samples were then oxidised in a furnace at 550 ºC for 2 hr. Calcination at 800 ºC for 20

188 hr was used to remove the biopolymer template and any residual organic residue. No other

189 processing steps were needed.

190

Water Contact Angle

192 Water contact angle measurements were obtained using the Ossila Contact Angle Goniometer

193 (error $\pm$ 1°) and accompanying software Ossila Contact Angle v1.0. A deionised water droplet

194 (5 µL) was delivered to the coated surface by a calibrated variable pipettor. Contact angles

195 were measured in triplicate as a function of time. Measurements were taken at 10 s intervals

196 over 160 s including measurements at 0 and 160 s.

197

198 **Results and Discussion**

199 **Single Polymer Solution Thin-Films**

200 AFM images (see **Figure S1** in Supporting Information) showed that thin-films cast from the

201 two individual biopolymers (Ch and BSA) did not produce any phase separated patterns. Neat

202 BSA films were totally featureless (**Figure S1**), while Ch showed partially aggregated

203 structures, likely due to its limited solubility. Glass slides were smooth and featureless. This

204 shows that features present in subsequent composite biopolymer films are due solely to the

205 composite formation mechanisms and not due to structures from an individual biopolymer.

206 This is consistent with our previous findings.[34]

207

208 **BSA-Ch Thin-Films**

209 *Thin-films from Phase Separation of BSA-Ch-FA Solutions*

210 Phase separation in polymer blend systems is the development of two distinct regions (phases)

211 of polymers from an initially homogenous solution. Similar to oil and water, polymers which

212 are incompatible separate from one another. Dissolving biopolymers in an acid protonates the

213 polymer chains, promoting segregative phase separation.[15] Upon separation, topographical

214 features develop as the film dries as the system attempts to minimize surface energy. Typically,

215   spheres or pores are formed as they have the lowest surface area to volume ratio. These features

216   grow as the system continues to minimize total surface energy. [44], [45]

217   **Figure 1** shows AFM images of BSA-Ch blend films. High resolution images each blend are

218   provided in **Figure S2 – S6,** with accompanying line profiles provided in **Figure S7 – S11** in

219   Supporting Information). Pores formation in the 4:1 and 2:1 BSA-Ch blend formed through

220   different mechanisms. Pores are discussed in the supplementary information.

221   In the 4:1 BSA-Ch blend, increased spin speed inhibited protuberance (spherical bumps)

222   growth, resulting in smaller, more homogeneously dispersed spheres. Feature diameter and

223   density data (represented as mean±standard deviation, **Figure 2** and **Figure S12**) shows

224   increased spin speed decreased protuberance diameter, and increased protuberance number per

225   area (protuberances/μm^2). This follows the general trend observed for all films. Mean

226   protuberance diameter decreased from 2.91 µm (500 rpm) to 0.81 µm (4000 rpm) (**Figure 1**,

227   A1 – A5). The 4:1 BSA-Ch blend was the only blend to contain salami structures $\geq$ 50 µm

228   (**Figure S13** in Supporting Information). Deposition at 500 rpm of the 4:1 blend resulted in

229   dewetting, attributed to the feature length approaching film thickness.[17] This is known to

230   occur during the latter stages of, and interfere with, phase separation. Low spin speeds when

231   casting films allows more time for phase separation to occur, causing feature diameter to

232   exceed film thickness (**Figure S12, Figure S14** in Supporting Information), leading to the

233   salami structure. The discontinuous salami domain is composed entirely of protuberances.

234   Pores are localised outside perimeter of the salami domains. The formation of the salami

235   morphology at this blend ratio may explain the variation in growth mechanism compared to a

236   high polysaccharide content blend (see below). This indicates that pores within the BSA

237   domain (and protuberances contained within the discontinuous Ch domain) are controlled by a

238   secondary phase separation process, which is consistent with our observations of film thickness

239   [17], [46]. Lastly, in the 4:1 blend, higher spin coating speeds resulted in thinner samples, as

did blend solutions with lower viscosity (lower w/v% solutions, **Figure S14** in Supporting

241 Information for further details).
Figure 1: AFM image grid showing results of casting thin-films at 65 % relative humidity from specific Pr-Ps (protein-polysaccharide) solutions of BSA-Ch-FA at various spin speeds. Each image is 40 μm × 40 μm area (scale bar 10 μm, shown in 4:1 blend at 500 rpm). In the image, bright areas are higher and dark areas are lower. Line profile (blue lines) may be found in each image and its corresponding Figure S2 – S6 in Supporting Information. Column A = 4 w/v% BSA and 1 w/v% Ch (4:1), column B = 2 w/v% BSA and 1 w/v% Ch (2:1), column C =

1 w/v% BSA and 1 w/v% Ch (1:1), column D = 1 w/v% BSA and 2 w/v% Ch (1:2), column E

250 *= 1 w/v% BSA and 4 w/v% Ch (1:4). Row 1 = 500 rpm, row 2 = 1000 rpm, row 3 = 2000 rpm,*

251 *row 4 = 3000 rpm and row 5 = 4000 rpm.*

252 At all spin speeds, protuberances follow a general trend of decreasing mean diameter with

253 increasing spin speed (**Figure 2a**). As a result, BSA-Ch blend film root-mean-squared (RMS)

254 roughness of the films and surface area ratio (%) decreases with increasing spin speed,

255 discussed in more detail the Supporting Information (**Figure S15**). As protuberances are the

256 desired morphology, a simple, predictable and efficient method of controlling feature diameter

257 like this is highly advantageous.
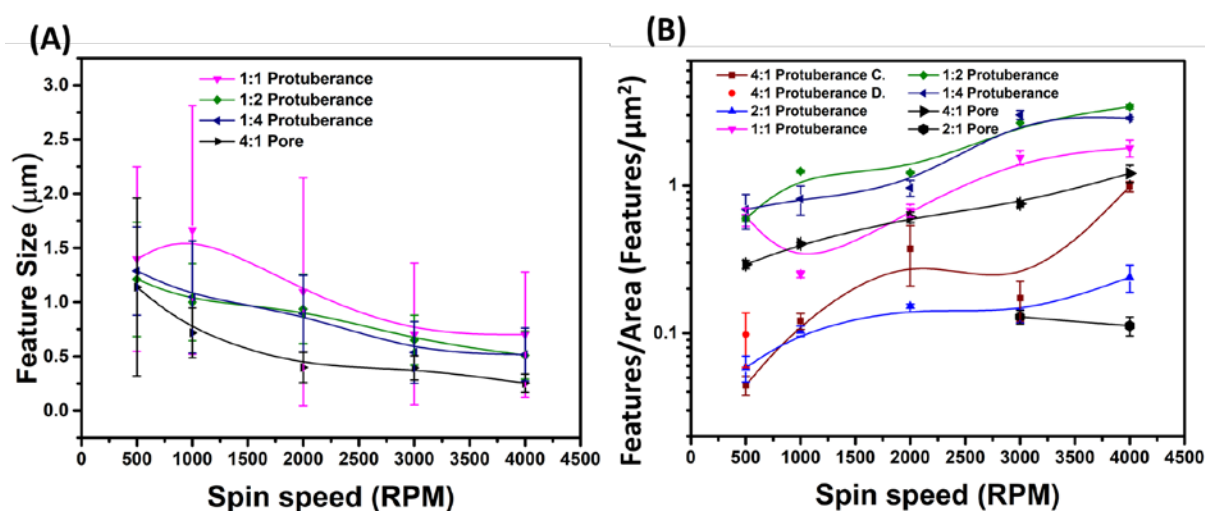

258

259 ***Figure 2:*** *Statistical analysis of BSA-Ch blends for feature diameter and feature number/area.*

260 *All but the 4:1 blend refers to protuberance measurements, with the 4:1 and 2:1 blend data*

261 *displaying both protuberance and pore data separately. The circular legend for the 4:1 blend*

262 *refers to feature diameter in the discontinuous domain, i.e. salami structure regions. **A)** Refers*

263 *to feature diameter plotted against spin speed while **B)** details features/μm^2 vs spin speed for*

264 *4:1, 2:1, 1:1, 1:2 and 1:4 blends respectively.*

265

266   **Figure 1** Column B contains the most visually distinct film structures, with the largest

267   protuberances of any blend formed. **Figure 1**, B1 and B2, show that increasing the film casting

268   spin speed of 2:1 BSA-Ch blends reduced mean protuberance diameters from 2.91 µm (500

269   rpm) to 1.60 µm (1000 rpm). The same increase in rpm also narrowed protuberance size

270   distribution (SD), from 1.5 µm – 6.1 µm to 0.7 µm – 3.2 µm. Spin speeds above 2000 rpm

271   produced a mixed porous/protuberant (**Figure 1**, B3 – B5). Protuberance diameter decreases

272   from 1000 rpm to 3000 rpm (1.6 µm to 0.81 µm). This reduction in protuberance diameter is

273   less than the initial reduction from 500 to 1000 rpm (**Figure 1**, B2 – B4). Protuberance mean

274   diameter increases at 4000 rpm (**Figure 1**, B5) to 0.99 µm. The increase in mean diameter is

275   likely due to shear at high speeds, as increased speeds should remove solvent quicker,

276   inhibiting growth. Spin speed thereby reduces the diameter of protuberances through faster

277   solvent evaporation and create larger ovoid protuberances (non-spherical protuberances

278   elongated on one axis) through shear forces, similar to the pore effect described in the 2:1 blend

279   [18]. The number of protuberances per area increased linearly from 500 rpm to 4000 rpm with

280   increased spin speed (**Figure 2b**). The submicron features in **Figure 1** are smaller than most

281   biopolymer blends in the literature (typically 10 µm in diameter and above). We attribute our

282   smaller features to the chosen biopolymers, spin speed, and chosen solvent.[12]

283   Solvents likely play a large role in forming the large features typically associated with

284   biopolymer thin-films morphologies and other structures produced from biopolymer blends.

285   Slowly evaporating blends produce large scale features.[23]˙[47] Low vapour pressure (non-

286   volatile) solvents evaporate slowly, while high vapour pressure (volatile) solvents evaporate

287   quickly producing smaller feature sizes.[47]˙[48] This may explain why biopolymer blends

288   produce large features, as water is the typical solvent. [12], [49]–[51] De Jong & van de Velde

289   segregatively phase separated whey protein/polysaccharide blends using water. Features were

290   5 – 10 µm in size.[12] PS/PEG blends use toluene, which is much more volatile than water,

291 producing features 200 – 400 nm in diameter.[40] Furthermore, using toluene as a solvent (less

292 volatile) produces larger features than chloroform (more volatile).[47]

293   When the quantities of protein and polysaccharide are approximately equal (1 w/v% BSA

294 to 1 w/v% Ch (**Figure 1**, Column C)) an intermediate state is seen, where larger, coalesced

295 features are observed, but a continuous phase is not sufficiently formed. Protuberance diameter

296 initially increases from approx. 1.40 µm to 1.67 µm with spin speed increase from 500 to 1000

297 rpm (**Figure 2a**). This is in conjunction with a sharp decrease in protuberances per area (**Figure

298 2b**) suggesting a growth process. From 1000 rpm to 4000 rpm (**Figure 1**, C2 – C5),

299 protuberance diameter decreases from 1.67 µm to 0.71 µm, while the number per area increases

300 (**Figure 2b**). This data shows that reducing the time for solvent loss produces smaller

301 protuberances and that there is a large degree of control over pattern formation. However,

302 above 1000 rpm protuberances are more irregular and less circular in shape. While the 1:1

303 BSA-Ch blend produces smaller protuberances than previously discussed blends, higher speeds

304 introduce an undesired pattern inhomogeneity. Increasing spin-coating speed from 2000 rpm

305 to 4000 rpm results in increased average diameter of these irregular protuberances (2.6 – 6.0

306 µm). These features appear similar to high spin speed 2:1 blends (**Figure 1**, B2 – B5). The

307 1:1 blend at 2000 rpm (**Figure 1**, C3) adopts a morphology similar to 2:1 blend at 1000 rpm

308 (**Figure 1**, B2) with larger protuberances interconnecting to form irregularly shaped ovoids.

309 3000 rpm (**Figure 1**, C4) produces flatter, larger, more branched features, similar to 2:1 BSA-

310 Ch blends at 2000 rpm (**Figure 1**, B3). This effect is further exaggerated at 4000 rpm (**Figure

311 1**, C5). We attribute this to higher shear stresses on larger structures at higher spin speeds.

312

313   Reduction of the BSA ratio from 2:1 to 1:1 (**Figure 1** Column C, **Figure S4**) results in

314 insufficient protein quantity to form a continuous phase as in **Figure 1** B3, *i.e.* phase inversion

315 does not occur preventing the pseudo pores seen in the 2:1 blend. This indicates that high

316 protein concentration is required for pore formation. The reduction of protein content to 1

317 w/v% produced a more monodisperse sample, and provided smaller feature diameters than 2:1

318 and 4:1 BSA-Ch blends, both desirable traits for patterning surfaces. Equally, the reduced BSA

319 content produced smaller protuberances, as did higher spin speeds. Complicating things

320 further, spin speeds above a certain maximum elongate the larger structures on the surface; that

321 maximum is blend dependant. The reduction of BSA w/v% (in contrast to the 2:1 and 4:1

322 blends) produces smaller BSA domains as less material is present to form these domains.

323 While mean diameter reduces with increased spin speed, larger domains increase in diameters

324 under shear with increased spin speed. Never-the-less, the 1:1 BSA-Ch blend results

325 demonstrate the ability to easily control feature diameters and features/area. This is vital for

326 maximising applicability. Use of patterned biopolymer films in a broad range of applications

327 necessitates the ability to produce an equally broad range of features diameters and

328 frequencies.[33]

329

330 1:2 (**Figure 1**, Column D and **Figure S5**) and 1:4 blends (**Figure 1**, Column E and **Figure S6**)

331 follow the simplest, and near identical, trends. Protuberance diameter decreases linearly while

332 increasing spin speed for both blends, with diameters generally smaller for the 1:2 BSA-Ch

333 blend. Mean protuberance diameter ranges from 1.21 - 0.51 µm for 1:2 blends compared to

334 1.29 - 0.52 µm for 1:4 blends, with spin speeds increased from 500 to 4000 rpm. Both the 1:2

335 and 1:4 blends show feature diameters smaller than 1:1, 2:1 and 4:1 blends. The increased

336 concentration of the continuous phase (Ch) increases viscosity, limiting coalescence thereby

337 reducing feature diameter.[33] The primary differences lie in the histograms for both blends,

338 with the 1:4 blends showing better defined peaks at higher spin speeds, indicating inhibited

339 growth.[52] Both blends exhibit little growth in protuberances per area until a large increase

340 is observed from 2000 - 3000 rpm (**Figure 2b**). This demonstrates that biopolymer blends may

341 be treated the same way as traditional polymer blends, meaning biopolymer blends can be

342 processed with pre-established techniques. Further, this method of producing a patterned

343 surface with biopolymer blends is much quicker than previously discussed techniques, and

344 produces features of approximately 1 μm.[34] This is much smaller than other bottom-up

345 biopolymer techniques, and is similar to blends produced with synthetic polymers [40], [53]–

346 [57].

347

348 *Chemical characterisation of BSA-Ch blend films*

349 Immersing coated substrates in a basic aqueous solution selectively dissolves the readily water-

350 soluble BSA. This allows for selective removal of the protein. **Figure 3a** shows a neat the 1:1

351 BSA-Ch blend, while **Figure 3b** shows both the large and small BSA domains removed from

352 the Ch matrix. Line profile analysis shows that larger domains do not penetrate directly to the

353 substrate, but are suspended in the Ch matrix. Smaller spherical domains protrude much deeper

354 into the Ch domain confirming late stage dewetting. Many of the pores in **Figure 3b** contain

355 extruded rims extending from the surface, producing a crater shape. This provides insight into

356 the protuberances formation mechanism. Coalescence of droplets is generally broken into four

357 steps: (i) droplet approach, (ii) matrix drainage between droplets, (iii) breakup of the matrix

358 film and (iv) relaxation of coalesced droplet into spherical shape.[58]–[60] Drainage of the Ch

359 matrix is observed in smaller BSA protuberances in contact with larger BSA domains.

360 However, many pores retain this crater morphology (*Figure 3c*). Other work on polymer

361 blends has shown these sharp, elevated rims occur when the continuous phase climbs around

362 the discontinuous droplets, *i.e.* pinning of the triple-phase protein-polysaccharide-air boundary,

363 droplet breakup, and resultant inhibited growth. [61], [62] Note that the features in our etched

364 BSA-Ch blend are over thirty times smaller than those of polystyrene/poly(methyl

365 methacrylate) blends, and are equivalent to polyfluorene blends.   This was seen in other blends

366 (**Figure S16** in Supporting Information) with rim height approx. 40 nm.

367 When using BCPs to pattern metals, metal is incorporated in to a single domain due to

368 the different chemistries of each BCP block.[63]   Ch is well known for its metal binding

369 capacity, due to the free electron pair on the amino group.[64]–[67] $FeCl_3$ was chosen as the

370 metal incorproate, as the amino group of Ch will chelate hard cations such as Fe^{3+}.[68] Unlike

371 Ch, BSA binds to soft metal cations.[37] $FeCl_3$ was chosen as the metal incorporate for a

372 second reason. Metal anions can promote, or inhibit, the binding of metal cations to proteins.

373 In particular, the Cl^- anion has a low affinity for BSA, as it is weakly hydrated. This effect is

374 described by the Hofmeister series.[69], [70] By choosing $FeCl_3$ as the metal precursor, both

375 the hard nature of the metal cation, and weakly hydrated nature of the metal counter-anion,

376 ensure that metal is incorporated only into the Ch domain. This allows for identification of the

377 Ch phase. Water was not chosen as a solvent for $FeCl_3$, as BSA is soluble in water. Using

378 water as a solvent for metal incorporation would result in the solubilization (and removal) of

379 BSA during the metal incoproation step, interfering with the identification of the Ch phase.

380 The use of anhydrous EtOH ensures the BSA domain is not solubilized. Though the number

381 of factors considered may seem excessive, trying to incoproate metal into a singular

382 biopolymer domain is no small feat. **Figure 3d** confirms that the continuous phase is Ch due

383 to the Fe_3O_4 uptake mirroring the BSA-Ch blend. Large BSA ovoid protuberances are reflected

384 as large irregularly shaped voids (large areas absent of metal uptake) in **Figure 3d**. Smaller

385 BSA protuberances are reflected as circular pores in the metallic film. Both the BSA etch and

386 metal incorporation do not reveal the bottom silicon substrate, indicating a thin layer of Ch

387 separates the BSA droplets from the substrate, blocking the Si surface, a feature observed in

388   almost all polymer blends.[53] Any application this may have as a hard mask would require

389   perforation of the BSA domain to the Si substrate, as the Si must be accessible to the etchant.

390   To the best of our knowledge, purely lateral phase separation of a polymer blend has only been

392
Figure 3*: AFM images and surface profiles of 1:1 BSA-Ch blends, 3000 rpm on planar silicon*

substrates. A) Refers to blend before Tris-HCl etch. B) Refers to blend post selective etching.

395   *C) Enhanced view of selectively etched BSA domains demonstrating extruded rim structure in*

396   *Ch film. D) Refers to blend post selective metal incorporation and calcination.*

397   **Figure 4A** shows FTIR transmission spectra of the biopolymer blend after various

398   processes. This was done to confirm chemical changes in the sample after BSA removal,

399   crosslinking, and calcination. For clarity of comparison, a bare Si wafer, plain BSA, and plain

400   Ch were analysed so that their identifying peaks could be differentiated from any unique to the

401   blend films. The bare Si wafer (**Figure 4A**, spectra i) has standard identifying peaks at 514 (Si–

402   O deformation)[71],   611 (Si–Si bond vibrations in the bulk)[72], 739 (O–H out of plane

403   bending)[71], 891 (Si–O–H mode due to oxidation of upper silicon layer)[72] and 1108 cm^{-1}

404   (Si–O–Si asymmetric stretching).[73] The shape and intensity of these peaks are similar for

405   all samples**.** The neat BSA film spectrum (**Figure 4A**, spectra ii) contained a weak band at

406   1376 cm^{-1} due to CH_3 symmetric bending.[74]   The amide I, and amide II modes of BSA were

407   observed at 1656 cm^{-1} and 1544 cm^{-1} respectively.[74] The amide II' transmission band is seen

408   at 1448 cm^{-1}.[75] The peak at 3208 cm^{-1} can be assigned to asymmetric and symmetric H–O–

409   H stretching, resulting from residual water in the film after casting.[74] Peaks in the Ch spectra

410   (**Figure 4A**, spectra iii) are observed at 1718 cm^{-1}, 1573 cm^{-1} and 1374 cm^{-1} corresponding to

411   the amide I, amide II, and amide III bands, respectively.[74], [76], [77] The peak at 1445 cm^{-1}

412   ^{1} can be assigned to an N-H bending of Ch. [78], [79]

413   The 1:1 blend (**Figure 4A**, spectra iv) exhibited no new peaks indicating no new bonds

414   occur. The Amide II peak for the non-crosslinked BSA film and the non-crosslinked Ch film

415   becomes less prominent after crosslinking (**Figure 4A**, spectra v and vi). This indicates a

416   reduction in free amines after crosslinking and the formation of a Schiff base.[80]   After

417   crosslinking, the 1:1 BSA-Ch blend (**Figure 4A**, spectra vii) has a peak at 3264 cm^{-1}: this is

418   due to water retained in the film after nitrogen drying. The crosslinked 1:1 film's amide II

419   peaks are less prominent post crosslinking, confirming crosslinking occurred. As the peaks

420   appear similar to those in the neat biopolymer films after crosslinking, we can infer only

421   intramolecular crosslinking has occurred which would suggest no BSA remains on the film

422   after etching. This is expected as BSA is segregated from the Ch domain. However, some

423   small degree of intermolecular crosslinking may occur at the BSA-Ch interface, though this

424   may be below the detection limit of the machine.[10]
426 *Figure 4: A) FTIR spectra of **i**) bare silicon wafer, **ii**) 1 w/v% BSA film 3000 rpm deposition,*

427 ***iii**) 1 w/v% Ch film 3000 rpm deposition, **iv**) 1:1 BSA-Ch blend film 3000 rpm deposition, **v**) 1*

428 *w/v% BSA film 3000 rpm deposition crosslinked, **vi**) 1 w/v% Ch film 3000 rpm deposition*

429 *crosslinked, **vii**) 1:1 BSA-Ch blend film 3000 rpm deposition crosslinked, **viii**) 1:1 BSA-Ch*

430 *blend crosslinked film after Tris-HCl etch and **ix**) porous iron oxide matrix after annealing and*

431 *calcination treatment. **B**) Shows the XPS Fe 2p spectra of iron porous matrix after annealing*

432 *and calcination treatment.*

433 The spectra of the etched film (**Figure 4A**, spectra viii) after crosslinking retains the BSA

434 peaks. This suggests residual BSA on the surface due to intermolecular crosslinking, or after

435 washing. Calcination of the BSA-Ch blend after metal incorporation results in a spectra with

436 no characteristic peaks of BSA or Ch, indicating their removal (**Figure 4A**, spectra ix). The

437 more prominent Si–O–Si band at 1108 cm^{-1} after calcination indicates a thicker oxide layer

438 than the native oxide of the original Si wafer. This is further confirmed by the peak in the bare

439 Si wafer (1237 cm^{-1}) shifting to 1245 cm^{-1}, which occurs when oxide thickness increases, a

440 consequence of the long calcination time and high temperature required to ensure complete

441 biopolymer removal.[81] This peak corresponds to the longitudinal optical phonon of SiO_2

442 (LO) around 1250 cm^{-1}, which occurs in thermal oxides.[82] Fe peaks were not observed at

443 630 cm^{-1} or 540 cm^{-1}, characteristic of magnetite and hematite respectively. FTIR confirmed

444 successful crosslinking of the biopolymer film before etching and successful removal of the

445 biopolymers after calcination.[83]

446 XPS was used to determine whether the iron present was predominantly hematite or

447 magnetite to confirm metal incorporation and oxidation (**Figure 4B**). The chemical

448 composition of the iron oxide matrix before/after annealing and calcination was confirmed by

449 Fe 2p XPS studies. Following calcination, the Fe 2p core level spectrum (see **Figure 4B**)

23

450 consists of two sharp peaks at 711.6 eV (Fe $2p_{3/2}$) and at 725.7 eV (Fe $2p_{1/2}$) which are

451 broadened due to the presence of Fe^{2+} and Fe^{3+} ions. Curve-fitting using Gaussian–Lorentzian

452 line shapes provides individual binding energies of 710.7/724.3 eV (assigned to Fe^{2+}) and

453 712.0/726.0 eV (Fe^{3+}) in agreement with literature reports.[84]   The Fe^{3+}/Fe^{2+} ratio was

454 estimated to be approx. 2:1, typical of magnetite. The C1s peak is nominal demonstrating the

455 effective removal of biopolymeric material during calcination, and is consistent with

456 extraneous carbon species adsorbed during sample preparation (**Figure S17** in Supporting

457 Information).

458 **Protuberance Growth in Blend Thin-Films**

459 Feature diameter determines the properties of a surface, such as pattern transferability,

460 hydrophobicity, etc. SDs can be used provide insight into film features and their growth

461 mechanisms[52]. This allows control of feature formation to optimise films for specific

462 applications. Protuberance diameter data was extracted from AFM images and presented as

463 SDs in normalized frequency histograms (**Figure 5**). Information about pore diameter and

464 mechanism of pore formation can be found in the Supporting Information (**Figure S18**). All

465 blends exhibit multimodal SDs with protuberances of large diameter at low spin speeds.

466 Increasing spin speed reduces the number of modes and shifts population weight to narrower

467 diameters, further indicating a nucleation and growth process. This also indicates that faster

468 spin speeds, up to certain thresholds, produce more homogenously distributed features of more

469 uniform diameter. This is crucial to production of effective patterned thin films. The 2:1 BSA-

470 Ch blend at 4000 rpm (**Figure 5b**) is an exception to the above, exhibiting a bimodal SD with

471 peaks at 1.3 µm and 1.5 µm protuberance diameters. This is likely due to shear effects at higher
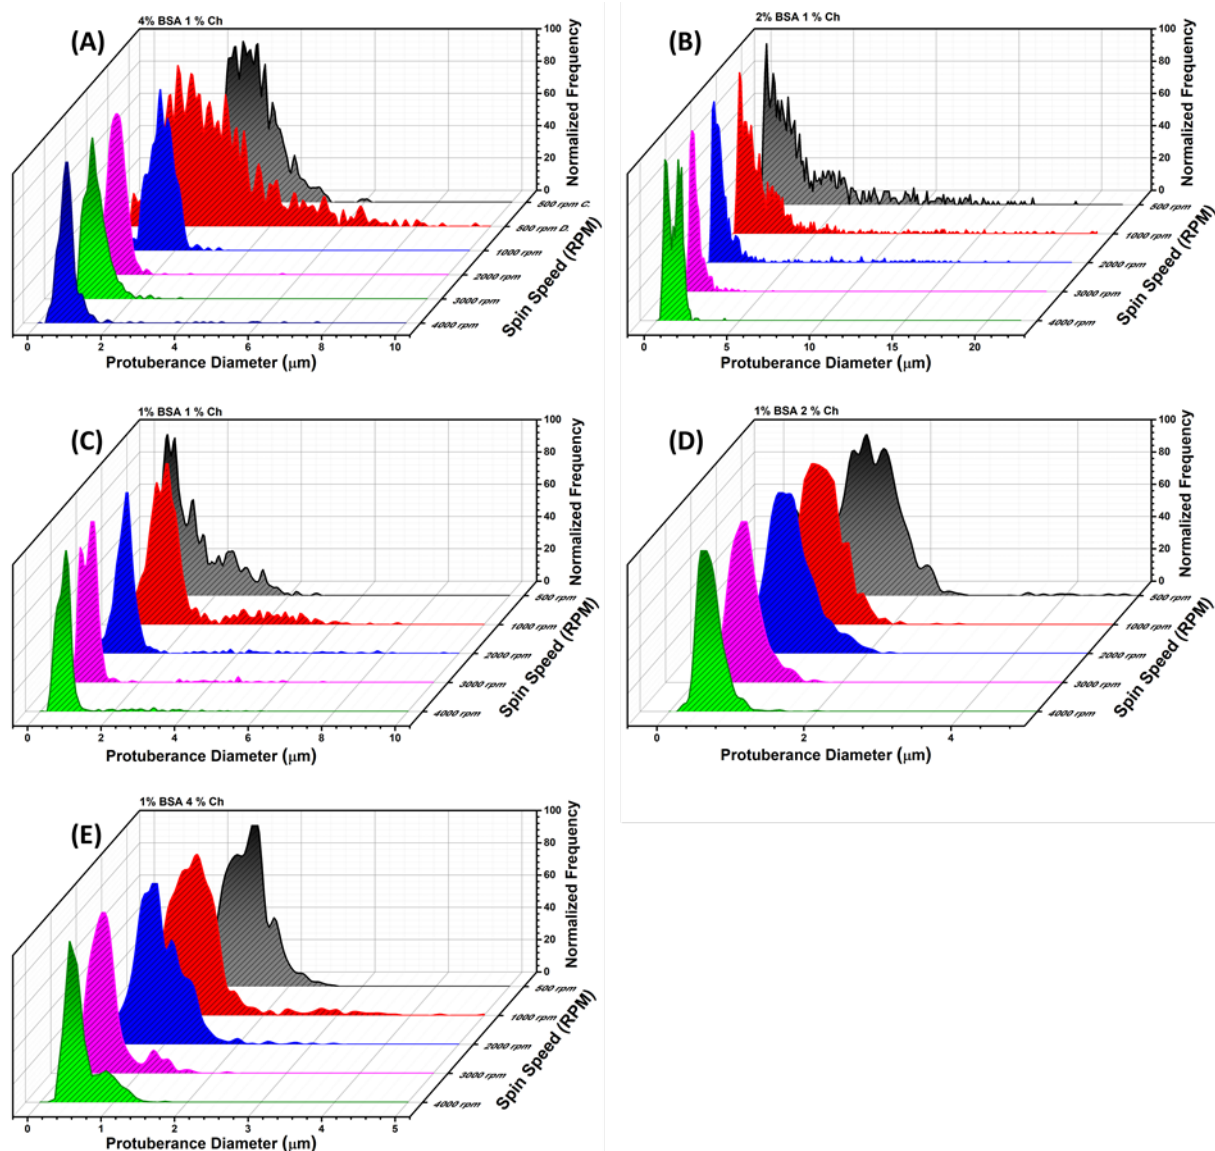

472 spin speeds.

473

474

Figure 5: *Statistical analysis of BSA-Ch blends for protuberances and frequency of protuberance sizes. Each curve based on approx. 1000 protuberance diameter measurements. All but the 4:1 blend refers to protuberance measurements contained within the matrix, with the 4:1 blend data displaying protuberance data for the continuous and discontinuous (salami structure) domain. **A – E** displays feature frequency vs diameter of observed features for 4:1, 2:1, 1:1, 1:2 and 1:4 blends respectively.*

481

482   Ostwald ripening occurs by the transfer of material from smaller features to larger

483   features by diffusion. The result is smaller features reducing in diameter while larger features

484   increase in diameter.[52] This is distinct from coalescence, where multiple spherical features

485   merge to form a larger version of the feature with lower surface area to volume ratio. Ostwald

486   ripening results in broader SDs and is undesirable. SDs arising from these processes have

487   distinct identifiable characteristics. Curve fitting may be used to determine the modality of the

488   SD (either unimomodal or polymodal), identify the mode diameter (Mo), and centre of gravity

489   (Xc) of the identified peaks.[85] Typically, this includes the fitting of a lognormal curve to the

490   SD. [52], [85]–[88] Lognormal peak fitting was achieved using the non-linear least squares

491   method.[88], [89]

492
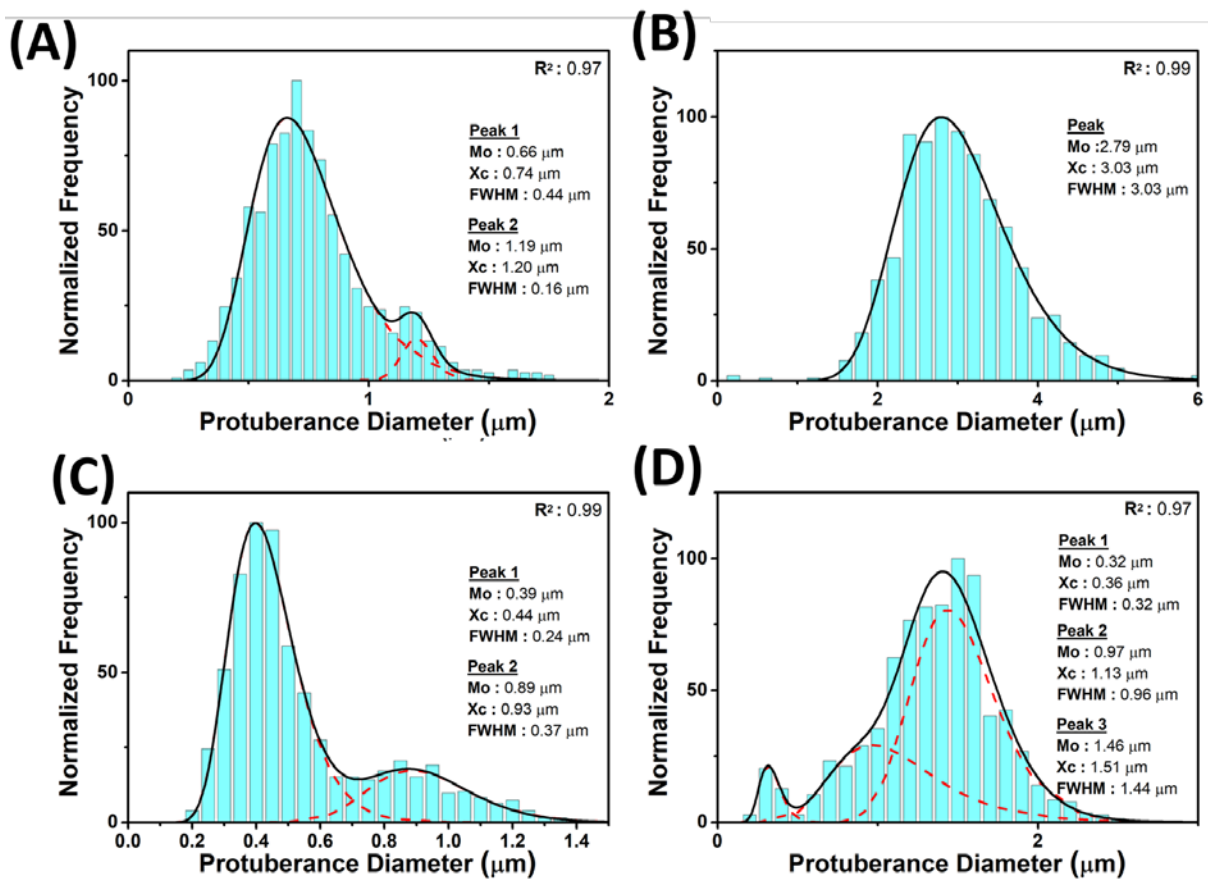

493   *Figure 6: Protuberance SD of A) 4:1 BSA-Ch blend, 4000 rpm deposition, B) 4:1 BSA-*

494   *Ch blend, 500 rpm deposition, C) 1:4 BSA-Ch blend, 4000 rpm deposition and D) 1:4 BSA-Ch*

26

blend, 500 rpm deposition. The black curve (solid) denotes the best unimodal or polymodal fit

with the distribution. The deconvouted peaks, shown in red (dashed), show the separate

populations in the SD.

498   The 4:1 blend exhibits coalescence characteristics; increased feature diameter and peak

499   broadening corresponding to longer evaporation times (**Figure 6a** and **b**). Additionally, the

500   SD transitions from a bimodal distribution to unimodal distribution.[90] In contrast, the 1:4

501   BSA-Ch blend exhibits Ostwald ripening characteristics; feature diameter increases with

502   longer evaporation time (**Figure 6c** and **d**), but formation of an extra peak (at approx. 0.3 µm)

503   is observed with longer drying time (Peak 1, **Figure 6d**), indicating production of smaller

504   particles, characteristic of Ostwald ripening. Increasing the concentration of Ch increased the

505   continuous phases viscosity, resulting in Ostwald ripening being the dominant growth

506   mechanism.[33]

507   These results show sub-micron features may be achieved using industrial standard

508   deposition techniques. This technique produces rapid pattern realisation, without requiring

509   extensive environmental controls such as temperature or humidity regulation. Feature diameter

510   and frequency/area are substantially similar to synthetic polymer blends. This means that

511   biopolymer blends could be incorporated into existing production processes for applications

512   where biopolymers offer a distinct advantage, with all the environmental and economic benefits

513   that come with using renewable resources. Furthermore, assignment of the protein and

514   polysaccharide domain was possible due to selective etching and metal incorporation. Both

515   techniques show promise as a method of identification of each domain (inaccessible to typical

516   staining techniques at such a small scale). This is simply achieved by the use of a crosslinking

517   agent, aqueous buffer and cheap metal additive, avoiding the use of expensive or specialist

518   enzymes for identification. The attraction of these techniques is the ability to identify each

519   domain without reliance on highly sensitive surface specific methods. Furthermore, these

520   techniques compliment other facile surface probing techniques such as water contact angle

521   measurements, which show clear differences when analysing the various surfaces encountered

522   (**Figure S19**). Though incorporation and etching provides insight into the internal structure

523   (and thereby formation mechanism) of the film, they do little to inform us of the chemical state

524   of the crosslinked blend at the interface.   Higher sensitivity ATR-FTIR would be required to

525   determine if crosslinking occurs at the interface. Deconvolution of the SD clearly shows the

526   presence of 2 growth mechanisms (Ostwald ripening and coalescence). Understanding of the

527   growth mechanisms is invaluable when choosing protein:polysaccharide ratios for surface

528   patterning. Selective incorporation of a metal salt could further be enhanced by use of other

529   metal salt derivatives, varying weight percentage of the salt type or varying contact time with

530   the blend film. It would be interesting to see if other salts could show preference to the protein

531   domain when incorporating into the blend film.

532

533   **Conclusion**

534   Spin speed and blend ratio are major factors when determining feature diameter, growth

535   mechanism and morphology. Blends generally showed a decrease in feature diameter and

536   roughness, while increasing in features per area with increasing spin speeds and polysaccharide

537   content. Faster drying times (high spin speeds) generally resulted in smaller features, while

538   longer drying times (low spin speeds) resulted in larger features. Simply put, faster spin speeds

539   increase the evaporation rate, limiting the amount of time features have to grow. Increasing

540   viscosity by increasing the relative Ch ratio reduced feature diameter due to lowered polymer

541   mobility. As Ch content is increased, it creates a viscous, honey-like matrix in which BSA

542   domain growth is hindered. Faster spin speeds resulted in more monodisperse blend SD's,

543   unless banding occurred due to shear effects at high speed. Protein:polysaccharide ratio played

544   an important role in determining morphology. Increasing the relative BSA ratio resulted in

545   larger BSA domains, and banding of the BSA domain at high shear due to the difference in

546   viscosity between the two phases.[18] Selective etching and selective incorporation of the

547   metal salts in the Ch domain allowed for protuberances to be assigned as the BSA domain, a

548   first for biopolymer blends. Coalescence was inhibited in 1:4 BSA-Ch blends due to the

549   increased viscosity of the blend, with feature growth described by Ostwald ripening. 4:1 blends

550   grew by a coalesence mechanism. 1:2 and 1:4 BSA-Ch blends have the smallest circular

551   protuberances. This is attributable to the blend solutions high viscosity and low amount of

552   BSA to form a discontinuous phase. The 1:1 blend smaller, circular features decrease in

553   diameter, while larger ovoid features increase in diameter at higher spin speeds (i.e. high shear).

554   This shows inhibited growth of the film morphology at higher spin speeds, and (similar to the

555   2:1 blend at 1000 rpm) an attempt to phase invert its morphology. Porous films are formed in

556   the 4:1 BSA-Ch blend. Pores decrease in diameter with increasing spin speed. Pores are

557   produced from a solvent rich phase. The 2:1 blend phase inverts at high spin speeds. After

558   phase inversion, pores increase in diameter with increasing spin speed due to high shear

559   elongating their domains.

560   This work demonstrates that protein-polysaccharide blends can be used to rapidly produce

561   biopolymer thin films with sub-micron patterns, all without requiring extracting, refinement

562   and production of synthetic polymer precursors. Due to their patterns, these unique biopolymer

563   thin-films present a vast spectrum of possible applications. These range from simple

564   applications including traditional packaging alternatives and smart foods production, to more

565   complex applications such as hydrophobic textile coatings, lithographic templates,

566   antireflective coatings, and state-of-the-art hierarchal designs used in biomedicine or

567   responsive membranes.[22], [33] Feature growth mechanisms were identified through analysis

568 of the SD. We did not find any previous attempts into the literature to determine the growth

569 mechanism, which may be one reason biopolymer blends thus far have had such large feature

570 diameters. Not only do these blends use environmentally benign and economically cheap

571 biopolymers, but they have feature diameters on a scale with those of synthetic polymer blends,

572 while utilizing industrially viable methods. This bottom-up method allows for instant pattern

573 production without the need for complex equipment and techniques such as e-beam

574 lithography. Patterns may be produced using benchtop equipment, without the long annealing

575 times associated with synthetic polymers. Biopolymer blends are projected to play a pivotal in

576 future manufacturing of biomedical, electronic, sensor and optical components. [22], [32], [33]

577 Research of into the properties of biopolymer blends thin-film surface morphologies is an

578 emerging field, and our method for producing these blends in a controlled manner is a

579 progressive step in the adoption of these films in modern technologies.

869
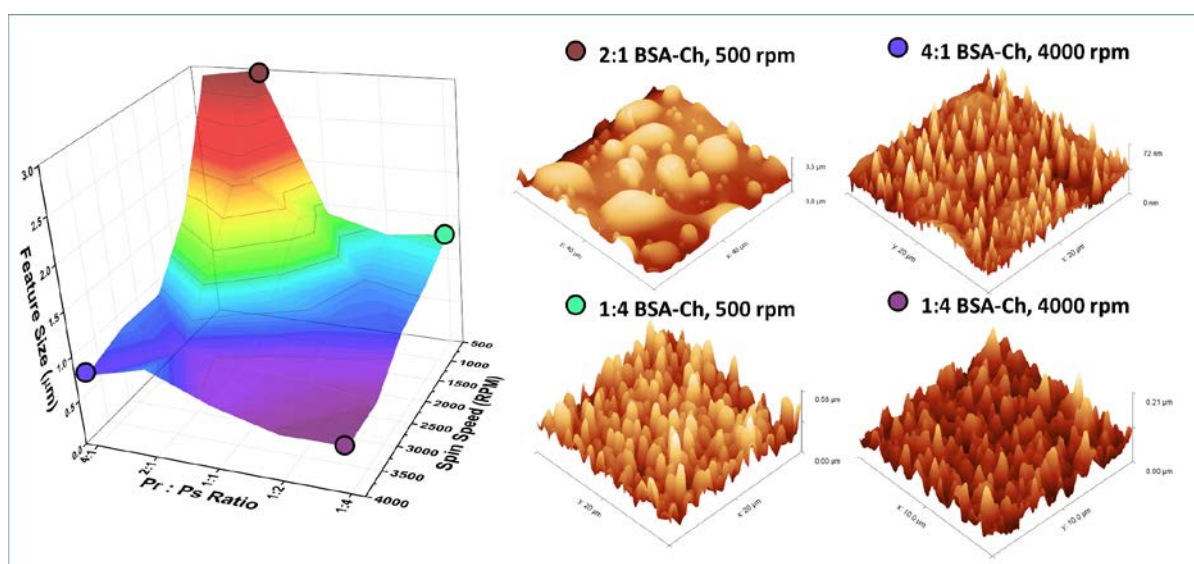

Supporting Information

871 **Solution Preparation**

872 Prior to dissolution, proteins, and polysaccharides were dried overnight at room temperature

873 under vacuum. Biopolymer stock solutions were made by solubilising Ch and BSA in 90 %

874 FA at 5 w/v%, 10 w/v%. These solutions were stirred in a closed vessel for 3 h at room

875 temperature. The solutions were then centrifuged at 13,000 rpm in a Beckman Coulter Avanti

876 J-26XPI centrifuge at 18 ºC for 15 min and decanted. Following this, stock solutions were

877 stored at -20 ºC for further use or used immediately. Stock solutions were diluted with fresh

878 FA and/or mixed with each other to produce coating solutions.

General Trends in Blend Thin-Film*s*
982   ***Figure S14:*** *Plots the average film thickness (nm) vs spin speed (rpm) for all BSA-Ch*

983   *blends.*

984

985   ***Figure S14*** shows the average film thickness of BSA-Ch blends. 1:1 BSA-Ch films are

986   the thinnest, due to low solution viscosity. Doubling the BSA wt % in the 2:1 BSA-Ch blends

987   increases film thickness due to increased solution viscosity. As Ch produces more viscous

988   solutions in formic acid, the 1:2 BSA-Ch blend produces thicker films than the 1:1 or 2:1 BSA-

989   Ch blends. Similarly, the 4:1 BSA-Ch blend is thicker than the 2:1 BSA-Ch blend. However,

990   at higher spin speeds (≥ 2000 rpm) 1:2 BSA-Ch blends have equivalent film thickness

991   measurements to 4:1 BSA-Ch blends. This is most likely due to faster evaporation during spin

992 coating resulting in more viscous solutions. This, in turn, would result in more Ch retained on

993 the substrate. As the most viscous solution, the 1:4 BSA-Ch films are the thickest. All blends

994 (with the exception of the 1:4 BSA-Ch blend) achieved minimal reduction in film thickness

995 with speeds exceeding 2000 rpm. The 4:1 BSA-Ch blend was the only blend to result in salami
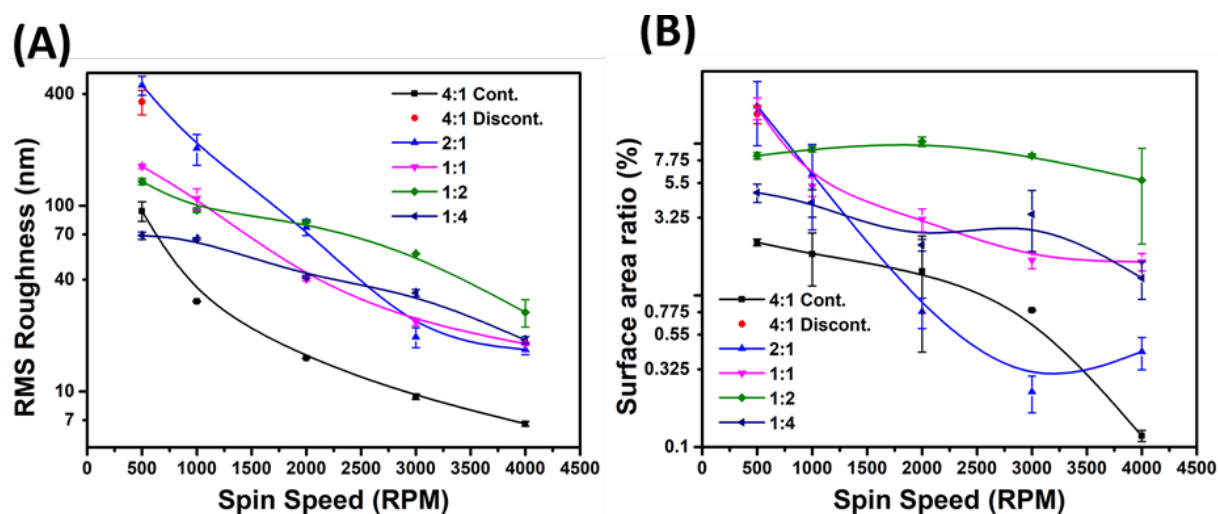

996 structure formation.

997

998

999 *Figure S15: A) Plots the RMS roughness vs spin speed for all BSA-Ch blends.* **B)** *Plots*

1000 *the surface area ratio (%) vs spin speed for all BSA-Ch blends.*

1001

1002 **Figure S15a** shows the BSA-Ch blend film RMS roughness as a function of spin speed

1003 for all samples. RMS of polymer blends can affect coating properties such as

1004 hydrophobicity[23] and wettability[91] and bacterial adhesion.[31] Therefore, tailorable RMS

1005 is desirable. In all blends, roughness decreased with increased spin speed. Slopes of the 4:1

1006 BSA-Ch blend were similar to the 2:1 blend, showing the sharpest reduction in RMS roughness

1007 from 500 rpm to 2000 rpm. For the 4:1 blend, this is likely due to a reduction in the diameter

1008 of all features as rpm increases. By contrast, the 2:1 blend loses large, tall features in favour

1009 of a smooth continuous BSA domain. At 4:1, 1:1, 1:2 and 1:4 ratios, protuberances become

1010   oblate, pancake-like structures with increasing spin speed, thereby reducing RMS roughness.

1011   This also occurs in the 2:1 BSA blend, but to a lesser degree. Transitions in spin speed from

1012   500 rpm to 1000 rpm reduced protuberance height from 4 μm to 600 nm resulting in the largest

1013   decrease in RMS roughness (242 nm, **Figure S15a**). However, a smooth continuous domain

1014   appears to be the predominant feature when determining RMS roughness for this blend.

1015   **Figure S15b** plots surface area ratio (%) as a function of rotational speed in spin coating.

1016   In general, surface area ratio (%) is reduced with increased spin speed due to the reduced height

1017   of the structures. This result shows that aspect ratio of features can be tuned, allowing broader

1018   applicability. Higher aspect ratios are particularly useful for enhancing anti-reflective

1019   properties. This aligns with previous data seen with RMS roughness in **Figure S15a**. The 1:2

1020   blend deviates from the general observation by increasing surface area ratio (%) with spin

1021   speed. This is due to interconnects (necks) forming between individual protuberances. As spin

1022   speed is increased from 500 rpm to 1000 rpm (**Figure 1**, D1 and D2), protuberance growth is

1023   inhibited by faster spin speed (**Figure 2a**). Protuberances however appear interconnected by a

1024   wall structure, referred to as a neck (i.e. inhibited coalescence).[58] As viscosity increases (due

1025   to increased concentration of the continuous phase) coalescence is supressed. This is to be

1026   expected as the adoption of a spheroidal shape is impeded.[40] These structures become more

1027   numerous as spin speed increases to 2000 rpm (**Figure 1**, D3) and growth is further inhibited.

1028   These interconnects increase the surface area ratio (%) of the sample. This is further supported

1029   by interconnects becoming less prominent at speeds exceeding 2000 rpm, though not totally

1030   removed (**Figure 1**, D4 and D5). In contrast to 4:1, 2:1 and 1:1 blends, the 1:2 blend features

1031   are compacted together and are not as well resolved from one another.

Pore Growth in Blend Thin-Films

1058

1059   At biopolymer ratio of 4 w/v% BSA to 1 w/v% Ch, across all spin speeds (**Figure 1**,

1060   Column A and **Figure S2**), pores (spherical holes) formed. Two relationships between pores

1061   and spin speed were observed: as spin speed increased, the mean pore diameter (**Figure 2a**)

1062   decreased and the number of pores per unit area (pores / μm^2, **Figure 2b**) increased. The mean

1063   pore diameter dropped from 1.14 μm (500 rpm) to 0.25 μm (4000 rpm), **Figure 2a**. Thus, pore

1064   formation at this biopolymer ratio occurs via an inhibited growth mechanism, *i.e.* a decrease in

1065   pore diameter with faster solvent removal.[23], [34], [40] The mechanisms of pore formation

1066   vary for each blend, unlike protuberances which show a consistent formation mechanism. The

1067   2:1 BSA-Ch blend only forms "pseudo pores" (discontinuous indented regions caused by

1068   dewetting and phase inversion) at spin speeds ≥3000 rpm, unlike in the 4:1 blend. [15], [18],

1069   [19], [34], [92], [93] An increase in spin speed increased pore diameter and decreased the

1070   numbers of pores per area (**Figure 1**, Column B and **Figure S3**). This is in contrast to the trend

1071   observed with the 4:1 BSA-Ch blend which showed a decrease in pore diameter and an increase

1072   in pores per area with increased spin speed (**Figure 1**, Column A) which suggests a secondary

1073   phase inversion rather than salami structure formation.[17], [94]

1074   Irregularly shaped pseudo pores are generated at ≥3000 rpm as phase inversion occurs

1075   (**Figure 1**, B3) due to the BSA component forming a continuous phase. Differences between

1076   the protein and polysaccharide phase viscosities at the 2:1 blend ratio, and strong shear forces

1077   at high spin speeds are the cause of phase inversion and phase elongation.[18][92] These shear

1078   stress effects also contribute to the increased pore diameter, the decreased number of

1079   features/area, and the irregular pore shapes.[18], [34] The pseudo pores observed in the 2:1

1080   BSA-Ch blend are much larger than that of the pores caused by solvent-rich phase evaporation

1081   in the 4:1 blend (**Figure 1** Column A and B, **Figure 2A**). This is due to pseudo pores arising

1082   during the BSA continuous phase formation and shear effects in the 2:1 blend, whereas "true"

1083   pores in the 4:1 blend appear to be formed from a solvent rich phase and solvent evaporation

1084   upon film vitrification.[53]

1085   **Figure 1**, image B5 shows that 4000 rpm yields small, circular pores. The larger pores

1086   form longer continuous phases resulting in a minor increase of mean pore diameter. This

1087   indicates that the 2:1 BSA-Ch blend pore growth mechanism differs to that of the 4:1 blend,

1088   resulting from the formation of a continuous BSA phase.

1089   Pore diameter data was also extracted from AFM images and the corresponding

1090   normalized frequency histograms are shown in **Figure S18**. The 4:1 BSA-Ch blend pores

1091   exhibited similar growth patterns to protuberances. At low spin speeds, the blends exhibit

1092   multimodal SDs over a broad diameter range. Increasing spin speed reduces the number of

1093   modes and population weight shifts to a smaller diameter (**Figure S18a**). This suggests that the

1094   pores, like the protuberances, develop via nucleation and growth. The 2:1 BSA-Ch blend

1095   produces a multimodal pore SD at high spin speeds (**Figure S18b**). These pores are irregularly

1096   shaped and do not form via the same process as 4:1 BSA-Ch blend pores (**Figure 1**, Column

1097   A).[26] They are caused by the BSA phase inverting and forming a continuous domain.[15]

1098   As such, increasing spin speed to 4000 rpm does little to shift the pore diameter, though the

1099   blend exhibits more pronounced peaks at 1.4 µm, 1.8 µm, 2.4 µm and 2.8 µm. It must be

1100   stated, however, that phase separation of polymer blends at high humidity and resulting pore

1101   formation is poorly understood.[26] Furthermore, humidity is not typically monitored,

1102   regulated or even discussed in the majority of polymer blend literature.[95] If pores are the

1103   desired morphological structure, removal of the discontinuous domain may be a more reliable
1104   manner of achieving a porous matrix.[57]

Water Contact Angle

Figure S19: *Displays plot of average receding contact angle as a function of time for*

BSA, Ch, BSA-Ch blend, Tris-HCl etched blend and porous iron oxide matrix.

Figure S19 shows water contact angles of the various relevant surfaces to confirm chemical and morphological changes in the samples with processing. This is to done to confirm the removal of BSA and the formation of a metal oxide on the surface to demonstrate correct assignment of each domain. All tested surfaces displayed a reduction in measured contact angle after 160 s. The 1:1 BSA-Ch blend exhibited the largest water contact angle, starting at 92° receding to 85°. This is unsurprising due to the rough nature of the blend surface and the incorporation of BSA, which is shown to have the second largest contact angle (85° – 79 °).[13] While on its own, water contact angle measurements do not confirm the removal of BSA or

1135 formation of the metal oxide, these results compliment the findings of the etching, metal

1136 incorporation, FTIR and XPS.

1137   The porous Ch matrix (73º – 64 º) has a higher contact angle than the pristine Ch surface

1138 (42º – 32 º): This is due to surface roughening caused by the pores. The reduction in the contact

1139 angle, compared to the 1:1 BSA–Ch, confirms the successful removal of BSA from the blend.

1140 Finally, the water contact angle of the iron oxide film (46º – 42 º) indicates magnetite

1141 composition, with the increased roughness and presence of pores contributing to a slightly

1142 larger contact angle than the literature.[96] The changes in the morphology and surface

1143 chemistry are as expected, and support the data seen in the FTIR and XPS spectra (**Figure 4**).
