The authors report a chemical process to remove the native oxide on Ge and Bi$_2$Se$_3$ crystals, thus facilitating high-resolution electron beam lithography (EBL) on their surfaces using a hydrogen silsesquioxane (HSQ) resist. HSQ offers the highest resolution of all the commercially available EBL resists. However, aqueous HSQ developers such as NaOH and tetramethylammonium hydroxide have thus far prevented the fabrication of high-resolution structures via the direct application of HSQ to Ge and Bi$_2$Se$_3$, due to the solubility of components of their respective native oxides in these strong aqueous bases. Here we provide a route to the generation of ordered, high-resolution, high-density Ge and Bi$_2$Se$_3$ nanostructures with potential applications in microelectronics, thermoelectric, and photonics devices.  

I. INTRODUCTION

Hydrogen silsesquioxane (HSQ) is a high-resolution, negative-tone, inorganic, electron beam lithography (EBL) resist, which is capable of producing high-density features in the sub-20 nm regime. Additionally, following electron beam exposure, HSQ physically and chemically, closely resembles SiO$_2$. This similarity to SiO$_2$ ensures that HSQ is inherently compatible with current microelectronics processing. To date, the use of HSQ has been largely limited to Si processing, although the application of HSQ to several other materials has been reported.

This article describes the application of an HSQ EBL process to single crystal Ge wafers, and Ge and Bi$_2$Se$_3$ thin films grown by molecular beam epitaxy (MBE). Literature reports on the application of an HSQ EBL process to these materials have detailed difficulties with the direct application of HSQ to their surfaces, and have attributed these difficulties to poor adhesion between HSQ and the surfaces of the materials. Consequently, there have been a number of reports identifying “adhesion promoting” interstitial layers such as Ti, Si, and Cr. This work identifies the cause of the reported “poor adhesion” and further concludes that, although HSQ does in fact adhere well to the surfaces of Ge and Bi$_2$Se$_3$, it is in fact the high solubility of the native oxides of these materials in the aqueous, basic, HSQ developer solutions that results in delamination of HSQ structures from the respective surfaces of Ge and Bi$_2$Se$_3$. The present work not only identifies why the need for HSQ adhesion promoters exists, but also details routes to apply HSQ directly to the surfaces of Ge and Bi$_2$Se$_3$, without the use of additional adhesion promoting layers. Adhesion promoting layers, such as those detailed previously, may not be compatible with all processes, e.g., metallization is typically avoided prior to device contact formation in front end of line lithography for integrated circuit fabrication. Consequently, the presence of additional adhesion promoting layers introduces the requirement for additional etching steps both prior to, and following pattern transfer to the device layer. Consequently, a technique such as that detailed herein may find favor when high-resolution lithography is required directly on Ge or Bi$_2$Se$_3$ surfaces or when a process compatible adhesion promoting layer does not exist.

Ge is an intrinsic group 14 semiconductor that offers a number of distinct advantages over Si for microelectronic device applications. Namely, Ge exhibits superior electron and hole mobilities relative to Si and has a lower band gap energy. Ge possesses a complex native oxide (GeO$_x$) consisting of GeO and GeO$_2$ components, as well as nonstoichiometric oxides. Both GeO and GeO$_2$ are soluble in tetramethylammonium hydroxide (TMAH) and NaOH. Consequently, if a GeO$_x$ layer exists between the Ge crystal and the HSQ EBL resist, dissolution of the underlying GeO$_x$ layer during development of the resist will result in lift-off of any high-resolution features written by EBL. Removal of the native Ge oxide is thus imperative prior to HSQ deposition, to facilitate the use of traditional aqueous HSQ developers. Although nonaqueous developers do exist for HSQ, these have been shown to offer significantly lower resolution than their aqueous counterparts.

Bi$_2$Se$_3$ has attracted much attention due to recently discovered topological insulating properties in the material.
Topological insulator nanowires and nanoribbons may have applications in quantum computing. Bi2Se3 has also been extensively studied for thermoelectric devices and infrared detector applications. Hicks and Dresselhaus proposed in the early 1990s that one-dimensional (1D) thermoelectric materials would display enhanced thermoelectric performance relative to bulk materials, due to reduced thermal conductivity in the 1D structures caused by confinement effects on the mean free path of phonons in the confined material. As a result, 1D thermoelectric materials, such as Bi2Se3 nanowires and nanoribbons, have been increasingly researched as potentially useful materials in next generation thermoelectric generators. Kong et al. recently showed that the native oxide on Bi2Se3 is composed of both BiOx and SeOx, and although the BiOx component rapidly forms on oxide free Bi2Se3 surfaces, the SeOx component forms slower. Importantly, at room temperature, the SeOx component of the native oxide is soluble in aqueous bases, whereas the BiOx component is not. Consequently, application of an HSQ EBL process to Bi2Se3 requires removal of SeOx prior to HSQ deposition. This work thus details a reproducible route to the production of high-resolution features on Ge and Bi2Se3 using an HSQ direct-write, negative-tone, EBL process.

II. EXPERIMENT

Ge substrates were patterned using the following approach. A 15 mm × 15 mm piece of p-doped (P, 10^{17} cm^{-3}) or n-doped (As, 10^{17} cm^{-3}) Ge (100) oriented wafer was first degreased via ultrasonication in acetone and iso-propanol (IPA) solutions (2 × 2 min), dried in flowing N2 gas and baked for 2 min at 120 °C in an ambient atmosphere to remove any residual IPA. Immediately prior to deposition of the HSQ resist layer the Ge surface was Cl terminated. The process used to achieve Cl termination was similar to that reported by Sun et al. First, the Ge wafer was immersed in de-ionized (DI) water for 30 s, and then 4.5 M HNO3 for 30 s followed by drying in flowing N2 gas for 15 s. The Ge piece was then immersed in a 10 wt. % HCl solution for 10 min. The wafer was then dried in flowing N2 for 10 s, and spin-coated (2000 rpm, 32 s, lid closed) with a 1.2 wt. % HSQ solution for 2 min prior to transferring to the EBL system for exposure. The sample was developed by immediately dispersing on the substrate and spin-coated as described previously. The sample was then baked at 120 °C in an ambient atmosphere for 3 min prior to transferring to the EBL system for exposure. The sample was developed by manual immersion in an aqueous developer solution of 0.116 M TMAH, 0.028 M NaOH, and 0.078 M NaCl for 15 s, rinsed in flowing DI water for 30 s, and dried in flowing N2 gas for 15 s. The HSQ pattern was transferred to the Bi2Se3 film using an Ar+ ion etch in an Oxford Instruments Plasmalab 100.

Scanning electron microscopy (SEM) was performed on a Zeiss Supra 40 FESEM. Transmission electron microscopy (TEM) cross sections were prepared using a standard focused ion beam (FIB) mill and lift-out technique on a FEI Helios Nanolab 600i dual-beam SEM/FIB equipped with an Omniprobe micromanipulator. TEM analysis was performed on a Joel 2010 high-resolution instrument with a LaB6 emission source operating at 200 kV.

III. RESULTS

Cl-terminated Ge was found to successfully eliminate the presence of an interfacial Ge oxide between the Ge substrate and the HSQ EBL resist. Elimination of the native oxide on Ge thus allowed for the production of ordered arrays of 20 nm wide HSQ lines directly onto the Ge surface. Figure 1 shows an SEM micrograph of 20 nm wide HSQ lines produced on Cl-terminated p-Ge. Figure 1 (inset) is an SEM micrograph of a Ge sample for which the native oxide was not removed prior to HSQ deposition and EBL exposure. Comparing the two SEM micrographs in Fig. 1, it is apparent that removal of the native Ge oxide prior to EBL is necessary to produce ordered arrays of high-resolution HSQ features on Ge surfaces. The requirement for removal of the native Ge oxide prior to EBL processing can be attributed to the high solubility of GeO2, and to a lesser extent GeO, in strong aqueous bases such as NaOH. When the sample shown in Fig. 1 (inset) was placed in the developer solution after electron beam exposure, the native Ge oxide between the Ge crystal and the exposed HSQ was dissolved. Dissolution of the native Ge oxide in the developer solution resulted in partial lift-off of the HSQ lines and consequently a loss of
order in the resultant HSQ mask as shown in the SEM micro-
graph in Fig. 1 (inset). Line edge roughness (LER) of the
20 nm wide HSQ lines (pitch 70 nm) was measured at 3.3 nm
(3σ) by analysis of high magnification SEM images using
IMAGEJ software. Details of the process used to calculate LER
are included in the supplementary material.22

Figure 2 shows Ge 3d core level XPS spectra for Ge
samples before and after chemical treatment to remove the
native Ge oxides. The Ge 3d peak has been deconvoluted to
reveal the contributions from the 3d_{5/2} and 3d_{3/2} levels in
Ge⁰, as well as higher oxidation states of Ge. Prior to chemi-
tical treatment to remove the native oxide there is an observed
broadening of the Ge 3d core level peak (FWHM 2.48 eV)
due to the contribution from GeOₓ, which results in addi-
tional blueshifted Ge 3d peaks relative to bulk Ge⁰. After
chemical treatment to remove the native Ge oxides the Ge
3d core level peak was observed to narrow (FWHM 2.08 eV)
as the contribution from higher oxidation states of Ge is
removed. Similarly, there was a significant change in the O 1s
core level spectrum (Fig. S2, in Ref. 22) before and after
chemical treatments to remove the native oxide. Although
there is a clear O 1s peak observed at ~532 eV in the sample
prior to chemical treatment, any signal due to O 1s was below
the level of the background noise of the spectrum after chemi-
tical treatment to remove the native oxide. The HSQ pattern
produced using the process outlined previously, was subse-
quently transferred to a p-Ge substrate using a Cl₂ RIE. An
example of a sample where the pattern was transferred to the
substrate is shown in Fig. 3. Figure 3 shows an SEM micro-
graph of 15 nm wide Ge fins at a pitch of 120nm. Details of
electron exposure doses for the HSQ mask used to produce
these structures are included in the supplementary informa-
tion (Fig. S3).22 The fins have been etched into the Ge wafer to a
depth of 20 nm. Figure 3 (inset) is an HRTEM micrograph of
a cross section of a 15 nm wide fin. The fin shown in the
HRTEM micrograph in Fig. 1 was purposely produced along
a (110) zone axis of the Ge crystal. The family of (110) axes
are known to offer the highest charge carrier mobility within
p-type Ge (Fd₃m crystal system), and are thus preferable for
device fabrication.23

Fabrication of arrays of high-resolution HSQ lines on a
Ge wafer using the HSQ EBL process, outlined previously,
was also observed to depend on the age of the HSQ resist.
HSQ has a shelf life of 6 months when stored in a sealed
container at 5°C. We have observed that the process for

![Fig. 1. HSQ lines, 20 nm wide, at a pitch of 70 nm, written on a Ge (100)
substrate at an area dose of 900 μC cm⁻². (Inset) HSQ lines, 20 nm wide, at
a pitch of 70 nm, written on a Ge (100) (GeOₓ surface) substrate at an area

20 nm. Fin length is 4.5 μm and fins are integrated with Ge pads (shown left
and right) in device-ready architecture. (Inset) A TEM micrograph display-
ing a cross section of one such 15 nm wide Ge fin.](image3)
producing high-resolution HSQ lines on Ge is reproducible and repeatable up to ~1 month after the stated expiry date. However, after this time, effects like those shown in Fig. 1 (inset) were observed, where exposed lines partially delaminate from the substrate during development. This observation suggests that the Si–H groups in the HSQ resist play an important role in the adhesion of the HSQ resist to the Cl-terminated Ge surface. As the HSQ resist ages, the cage-like oligomers within the resist cross-link forming a network structure with the evolution of hydrogen gas. The Si–H sites in HSQ have been reported to be the sites involved in HSQ cross-linking and network formation. Consequently, as the resist ages fewer Si–H sites are available to interact with the substrate to which the resist is applied. The fact that delamination of electron beam exposed HSQ lines from chlorinated Ge substrates is observed when HSQ ages beyond a certain point is thus indicative of cross-linking of the resist to the substrate.

Fourier transform infrared (FTIR) spectroscopy was used to investigate the presence of any chemical interaction between the HSQ resist and a Cl-terminated Ge substrate (Fig. S4), following electron beam exposure or thermal treatment. Figure S4 shows an FTIR spectrum of a 25 nm HSQ film deposited on a 20 nm Ge film prepared on a Si substrate by MBE (Ge–Si) prior to electron beam exposure or thermal annealing. Preparation of the Ge–Si substrates has been described elsewhere, and TEM analysis has confirmed the highly crystalline epitaxial interface between the Ge film and the Si substrate. The native Ge surface oxide was removed, and the Ge film was terminated with Cl prior to HSQ deposition. The spectrum in Fig. S4 was produced by subtracting the spectrum produced by a clean Ge–Si substrate from that of a Ge–Si substrate coated with a 25 nm HSQ film. The spectrum in Fig. S4 shows the hallmark absorbance peaks associated with HSQ. The Si–H stretch is observed at 2256 cm⁻¹, which is characteristic of a Si–H species, whereby the Si atom is bound to three electronegative O atoms leading to a blueshift in the Si–H absorbance peak relative to an Si–H species present on a hydride terminated Si wafer, for example. The asymmetric Si–O–Si stretching modes for cage and network HSQ structures have absorbance peaks labeled νas(Si–O–Si)ₙₐₜ and νas(Si–O–Si)ₖₐ₇ and are visible at 1122 and 1065 cm⁻¹, respectively, whereas Si–O bending modes are observed at 860 and 827 cm⁻¹ and are labeled d(H–Si–O) and d(O–Si–O), respectively. The bending modes d(H–Si–O) and d(O–Si–O) can be attributed to the cage and network structures, respectively, as reported previously. The greater intensity of the νas(Si–O–Si)ₙₐₜ and d(H–Si–O) absorbance peaks in Fig. S4 with respect to the νas(Si–O–Si)ₖₐ₇ and d(O–Si–O) peaks, respectively, is consistent with a high concentration of the cage species with respect to that of the network analog prior to electron beam exposure or high temperature thermal treatment.

Figure 4 displays FTIR spectra of 25 nm HSQ films on Ge–Si and Si substrates after annealing at 673 K for 1 h in a N₂ atmosphere. The HSQ changes upon heating are typical of the literature. Here we note that there is the addition of a Ge–O–Si peak, which we attribute to chemical bonding at the interface. This did not appear in electron beam exposed samples possibly due to insufficient signal. We expect its presence due to the potential for a condensation reaction at the interface between the Si–H bonds in the HSQ and the Ge crystal as highlighted in the upcoming Eq. (1). The peaks associated with the cage structure of HSQ seen in Fig. S are notably absent from the spectra in Fig. 4, these include the Si–H stretch, νas(Si–O–Si)ₙₐ₇, and d(H–Si–O) at 2256, 1122, and 860 cm⁻¹, respectively. The dominant feature of the spectra in Fig. 4 is the absorbance peak at 1060 cm⁻¹, associated with asymmetric stretching of the Si–O–Si moiety in a SiO₂ glass. Another feature present in the FTIR spectra of the HSQ films on Ge–Si and Si shown in Fig. 4, is the peak denoted with an asterisk (*) at 879 cm⁻¹ associated with a Si–O bending mode in a Si rich silicon oxide. The bottom trace in Fig. 4 represents the difference between the middle and top traces after baseline correction, and the broad absorption peak at ~1000 cm⁻¹ can be attributed to a combination of Si–O–Si and Ge–O–Si moieties. Spectra are offset arbitrarily along the absorbance axis for clarity.
those being the asymmetric Si–O–Si stretch at 1060 cm\(^{-1}\) and the Si–O bend at 879 cm\(^{-1}\). When the difference between the FTIR spectra obtained from the electron beam exposed samples was considered bottom trace in Fig. S5,\(^{32}\) only a very low intensity absorbance peak at 1030 cm\(^{-1}\) consistent with a Ge–O–Si vibrational mode\(^{29}\) was observed, however, this peak is almost at the noise level of the spectrum. Electron beam exposure of a larger area of HSQ film may facilitate detection of a more significant signal from the HSQ interface with Ge, however, this would require electron beam exposure times of a week or more for each of the Si and Ge–Si samples. Electron beam exposure and thermal curing of HSQ films have been shown previously to result in similar Si–H and Si–O bond redistribution effects, thus, thermal curing can be considered to produce comparable effects to electron beam exposure in HSQ films.\(^{3,30}\) Consequently, the Ge–O–Si moiety observed in HSQ films deposited on Cl-terminated Ge after thermal curing suggests that HSQ patterns produced on Cl-terminated Ge by EBL are covalently bound to the Ge crystal, thus preventing lift-off of high-resolution HSQ patterns during HSQ development. Direct cross-linking of HSQ films to the Cl-terminated Ge substrate is likely to be a dynamic process involving the hydrolysis of the Ge–Cl species by residual water remaining from the aqueous HCl solution used to chlorinate the Ge surface. Ge–OH species formed by hydrolysis of Ge–Cl would readily react with silanol groups present in the HSQ films during thermal annealing or electron beam exposure resulting in the formation of Ge–O–Si linkages via a condensation reaction as shown in the following equation:\(^{29}\)

\[
\text{Ge}_{\text{bulk}} - \text{Ge} - \text{OH} + \text{HO} - \text{Si} - \text{HSQ}_{\text{network}} \\
\rightarrow \text{Ge}_{\text{bulk}} - \text{Ge} - \text{O} - \text{Si} - \text{HSQ}_{\text{network}} + \text{H}_2\text{O}.
\]  

(1)

Figure 5(a) shows an SEM image of a cubic array of 20 nm diameter Bi\(_2\)Se\(_3\) disks at a pitch of 100 nm. Figure 5(b) displays an SEM image of 30 nm wide and 2 nm thick Bi\(_2\)Se\(_3\) nanoribbons produced using the HSQ EBL process outlined previously. The HSQ etch mask remains on top of the Bi\(_2\)Se\(_3\) structures in Figs. 5(a) and 5(b). Figures 5(c) and 5(d) show a comparison of HSQ lines exposed on an untreated Bi\(_2\)Se\(_3\) surface [Fig. 5(c)] and a Bi\(_2\)Se\(_3\) surface that has been washed with a NaOH/TMAH solution to dissolve surface SeO\(_2\) [Fig. 5(d)]. Comparing Figs. 5(c) and 5(d), it is again apparent that the presence of a surface oxide, which is soluble in the HSQ developer, inhibits the production of ordered arrays of high-resolution HSQ structures using an HSQ EBL process.

Figure 6 displays a selection of cross-sectional TEM micrographs of Bi\(_2\)Se\(_3\) nanoribbons produced from a 7 nm Bi\(_2\)Se\(_3\) film grown by MBE. The Bi\(_2\)Se\(_3\) film was patterned using the HSQ EBL process outlined previously and the pattern was transferred to the film using an Ar\(^+\) ion etch. Figure 6(a) displays 30 nm wide nanoribbons at a pitch of 60 nm produced from an 8 nm thick Bi\(_2\)Se\(_3\) film. Figure 6(b) shows an HRTEM micrograph of the crystal lattice of a single Bi\(_2\)Se\(_3\) nanoribbon. The HRTEM micrograph clearly shows the layered crystal structure of rhombohedral Bi\(_2\)Se\(_3\) with the c-axis of the crystal oriented orthogonally to the Si ⟨111⟩ substrate. The repeating units in the layered structure of the Bi\(_2\)Se\(_3\) thin films are known as quintuple layers (QL) and are stacked along the c-axis. Each QL is so-called as it consists of five layers of atoms in the sequence Se–Bi–Se–Bi–Se. Within each QL, strong covalent and ionic bonding dominates, however, only weak van der Waals-type bonding exists between the two Se layers at the QL–QL interface.\(^{31}\) The observed QLs in Fig. 6(b) are \~1 nm thick as described in previous reports. The Bi\(_2\)Se\(_3\) film thickness is an integer multiple of the QL period. Figure 6(c) shows an HRTEM micrograph of a cross section of an 18 nm wide, 7 nm thick, Bi\(_2\)Se\(_3\) nanoribbon. An amorphous layer of material is observed at the interface between the nanoribbon (dark region) and the Si substrate.

![Fig. 5](image1.png)

(c) HSQ lines, 20 nm wide, exposed at a pitch of 70 nm on an untreated Bi\(_2\)Se\(_3\) surface. (d) HSQ lines, 20 nm wide, exposed at a pitch of 100 nm on a Bi2Se3 surface washed with a NaOH/TMAH solution prior to HSQ deposition to remove surface SeO\(_2\).

![Fig. 6](image2.png)

Fig. 6. (a) Cross-sectional TEM micrograph of 30 nm wide, 8 nm high, Bi\(_2\)Se\(_3\) nanoribbons at a pitch of 60 nm. HSQ mask remains atop the Bi\(_2\)Se\(_3\) nanoribbons. (b) HRTEM micrograph of a cross section of a Bi\(_2\)Se\(_3\) nanoribbon. (c) HRTEM micrograph of a cross section through a Bi\(_2\)Se\(_3\) nanoribbon and the underlying Si ⟨111⟩ substrate.
in Fig. 6(c), which can be attributed to the formation of a layer of amorphous SiO$_2$, which is formed following MBE Bi$_2$Se$_3$ thin film growth. Amorphous SiO$_2$ formation can be attributed to the diffusion of oxygen through the Bi$_2$Se$_3$ thin film when the Bi$_2$Se$_3$ film is exposed to an ambient atmosphere.  

XPS analysis of a Bi$_2$Se$_3$ thin film sample before and after treatment with the TMAH/NaOH/NaCl solution revealed a change in the composition of the surface of the sample. A Bi$_2$Se$_3$ thin film, which had been stored in a chemical dehumidifier at room temperature for 6 months while waiting for further processing, was analyzed by XPS as shown in the upper spectra in Fig. 7. Deconvolution of the Bi 4f$_{7/2}$ and 4f$_{5/2}$ core level peaks reveals the presence of the Bi 4f$_{7/2}$ and 4f$_{5/2}$ peaks from Bi$_2$Se$_3$ at 157.4 and 162.8 eV, respectively (peak area ratio of 1.32 measured for 4f$_{7/2}$/4f$_{5/2}$). Further, the deconvolution reveals Bi 4f$_{7/2}$ and 4f$_{5/2}$ peaks blueshifted by 1.3 eV relative to the Bi 4f core level peaks attributed to Bi$_2$Se$_3$. These blueshifted peaks can be attributed to Bi interacting with a more electronegative species than Se, i.e., Bi$_2$O$_3$. The blueshift of 1.3 eV for Bi$_2$O$_3$ is consistent with recent observations reported for Bi$_2$Se$_3$ nanowires. Comparison of the 4f$_{7/2}$ core level peak areas for Bi$_2$Se$_3$ and Bi$_2$O$_3$ suggests a Bi$_2$Se$_3$/Bi$_2$O$_3$ ratio of 3/1. Consequently, when the relative densities of Bi$_2$Se$_3$ and Bi$_2$O$_3$ are considered, it can be inferred that the as-grown 8 nm thick Bi$_2$Se$_3$ film, should now exist as a 6 nm Bi$_2$Se$_3$ film capped with a 2 nm Bi$_2$O$_3$ layer. Figure 7 also shows XPS spectra of the Se component of the native oxide. The spectra shown in Fig. 7(a) display Se 3d core level peaks attributable to Se$^{2-}$ in Bi$_2$Se$_3$ at a binding energy of 52.8 eV. Deconvolution of the peak at 52.8 eV reveals contributions from the Se 3d$_{3/2}$ and 3d$_{5/2}$ levels at binding energies of 52.4 and 53.2 eV, respectively, suggesting a crystal field splitting energy of 0.8 eV. The sample analyzed prior to washing with the TMAH/NaOH/NaCl solution, also revealed a lower intensity Se 3d core level peak at a binding energy of 58.3 eV. The blueshift of the peak attributed to Se$_2$O$_2$ relative to that attributed to Bi$_2$Se$_3$ is a consequence of the large difference in oxidation of Se in the two species in question, Se$^{4+}$ in SeO$_2$ and Se$^{2-}$ in Bi$_2$Se$_3$.

**IV. SUMMARY AND CONCLUSIONS**

To conclude, successful chemical routes to remove the native oxides of both Ge and Bi$_2$Se$_3$ prior to the application of HSQ EBL resist have been demonstrated. The chemical processing of Ge and Bi$_2$Se$_3$ described herein is imperative to produce ordered arrays of high-resolution nanostructures in both of these materials using an HSQ EBL process. Consequently, where a material possesses a native oxide, which is soluble in HSQ developers, the limiting factors to achieving high-resolution HSQ nanostructures on the surface of such a material, is the availability of a viable route to remove the native oxide and the adhesion of HSQ to the oxide-free surface of the underlying material.

Further, a route to the production of covalently bound SiO$_x$ films on Ge has been demonstrated by thermal curing of HSQ films deposited on Cl-terminated Ge crystals. This route may find applications in the fabrication of Ge-on-insulator substrates, as well as in the production of low-$k$ dielectric films on Ge materials.
